Uricase was lost to man and some nonhuman primates via a missense mutation in the gene encoding the enzyme (see Chapter 94).¹⁹⁵ Pegloticase is a pegylated mammalian (porcine-like) recombinant uricase, recently approved by the FDA at a dosage of 8 mg intravenously every 2 weeks for the treatment of severe tophaceous gout.^{150,196} With intravenous administration of 0.5 mg to 12 mg, the plasma uricase activity increases linearly with doses up to 8 mg, with an enzymatic activity half-life of 6.4 to 13.8 days. With intravenous doses of 4 mg or more, the serum urate falls dramatically in 24 to 72 hours, from a mean of 11.1 mg/dL to 1 mg/dL and stays low for 21 days after infusion.¹⁹⁷ Pegloticase was studied in a phase I, a phase II open-label trial (41 patients), and two replicate phase III randomized control trials (212 patients total).¹⁹⁸⁻²⁰² In the phase III trials, subjects with treatment-failure gout were randomly assigned to either pegloticase 8 mg intravenously every 2 weeks or 4 weeks or placebo.²⁰¹ Pegloticase was significantly more effective than placebo at achieving the primary end-point of a plasma urate concentration lower than 6 mg/dL for 80% of the time in months 3 and 6 of the trial. It also seemed clear that, when tolerated, pegloticase was efficacious at reducing tophi (Figure 95-9).^{200,202} Colchicine or NSAIDs were used for gout prophylaxis, and oral fexofenadine and acetaminophen, as well as hydrocortisone 200 mg intravenously before infusion, were used for infusion reaction prophylaxis. Despite that, gout flares, infusion reactions, and serious adverse events were significantly more frequent in patients given pegloticase than in other patients. The most common reason for withdrawal was infusion reaction.

Important relations were noted among immunogenicity, infusion reactions, and efficacy.²⁰³ High-titer antibodies to pegloticase and/or polyethylene glycol were associated with loss of response and infusion reactions. In fact, 96% of patients with antibodies to poly(ethylene glycol) from the groups assigned every-2-week or every-4-week pegloticase were nonresponders, and 50% and 76%, respectively, had infusion reactions. These antibodies did not neutralize uricase activity in vitro. The development of these anti-pegloticase antibodies was associated with a loss of response in patients coinciding with a rise in plasma urate concentrations above 6 mg/dL.²⁰⁴ Tellingly, 71% of infusion reactions occurred after this loss of response. In the group assigned pegloticase every 2 weeks, cessation of treatment when concentrations of plasma urate were higher than 6 mg/dL would have avoided 91% of infusion reactions.²⁰⁴ Because of this observation, the FDA has recommended that clinicians follow serum urates carefully and stop pegloticase when the serum urate rises above 6 mg/dL. An open-label extension study with 151 patients supported the conclusions from the phase III trials.²⁰⁵ Gout attacks continued to decline in patients, most patients maintained target serum urates, and an additional 20 patients, beyond the 32 patients in the randomized trials, had complete resolution of at least one tophus. Unfortunately, infusion reactions remained common and sometimes serious, frequently leading to discontinuation, particularly in those who had only received placebo in the randomized trials.

Table 95-9 Effects of Probenecid on Metabolism of Other Drugs

Decreased Renal Excretion
<i>p</i> -Aminohippuric acid
Phenolsulfonphthalein
Salicylic acid and its acyl and phenolic glucuronides
Phlorizin and its glucuronide
Acetazolamide
Dapsone and its metabolites
Sulfinpyrazone and its parahydroxyl metabolite
Indomethacin
Ampicillin
Penicillin
Cephadrine
Reduced Volume of Distribution
Ampicillin
Ancillin
Nafcillin
Cephalexidine
Impairment of Hepatic Uptake
Bromsulfophthalein
Indocyanine green
Rifampicin
Delayed Metabolism
Heparin

Figure 95-9 Photographic and radiographic evidence of tophus resolution after pegloticase treatment. **A**, Large draining tophus on fifth distal interphalangeal (DIP) joint, before treatment. **B**, Corresponding radiograph showing soft tissue swelling and bony erosions in fifth DIP joint, before treatment. **C**, Resolution of tophus on fifth DIP joint after 12 weeks of treatment. **D**, Corresponding radiograph showing resolution of soft tissue swelling in fifth DIP joint, a decrease in bony erosions, and thickening of bone cortex at this joint, 15 months after termination of therapy. (From Baraf HS, Matsumoto AK, Maroli AN, Waltrip RW: Resolution of gouty tophi after twelve weeks of pegloticase treatment, *Arthritis Rheum* 58:3632, 2008.)

All patients in the pegloticase randomized trials had some cardiovascular risk factor.²⁰¹ There was a concern for an independent cardiovascular side effect signal in patients treated with pegloticase, but the FDA's independent analysis concluded that the number of events was too small to lend support to a definite cardiovascular signal.²⁰⁶ The FDA approved pegloticase for use in treatment-failure gout in October 2010. Pegloticase will have a more limited target population than febuxostat. Terkeltaub has proposed guidelines for the use of uricases in gout.²⁰⁷ They are appropriate for patients with tophaceous gout with a large excess of total body urate and persisting gout attacks, or with damaging arthropathy, who have failed or are intolerant of conventional therapy. Presumably, many patients who fit this description can now be given and will respond to febuxostat, but others will not. The notion of debulking the urate load is a good way to conceptualize the pegloticase strategy and emphasizes it as adjunctive therapy, best followed by other urate-lowering therapy when possible. A clear advantage is that pegloticase can reduce tophi dramatically and more quickly than conventional treatment^{200,202,205} (see Figure 95-9). Problems with immunogenicity continue, and the continuous use of pegloticase may be restricted by antibody development. At least 25% of patients develop antibodies, with subsequent infusion reactions, restricted

efficacy, or drug withdrawal. Anaphylaxis occurs in about 5% of treated patients. Gout flares are sometimes severe and are frequent, occurring despite prophylaxis in more than 80% of treated patients. The required concomitant infusion of corticosteroids with pegloticase may further restrict its use in patients with conditions such as diabetes or glaucoma, and pegloticase should not be given to patients with glucose-6-phosphate dehydrogenase deficiency because it may induce hemolysis.

Despite the potential downsides of pegloticase, previously these often terribly symptomatic patients had no options. Hopefully, monitoring for a rising serum urate concentration as a sign of antibody development and impending infusion reaction will allow for safer administration.²⁰⁴ Encouraging data recently presented in abstract form suggest that a subset of patients who normalize their serum urate within the first 6 months of pegloticase treatment can be safely maintained on therapy long term, with a median follow-up of 2.5 years.²⁰⁸ In addition to ongoing clinical improvement, the frequency of infusion reactions was low in this group, even in subjects with breaks in treatment of up to 6 months. Nevertheless, this is a drug that should be administered at centers familiar with its use and with an established capability of dealing with serious infusion reactions including anaphylaxis.

COMPLIANCE WITH TREATMENT

Because the disease processes involved in gout are so well understood, the diagnosis can be definitively established. Once gout is diagnosed, the available therapies are so effective that it should be a readily treated and easily managed disease. However, too many patients including those who are accurately diagnosed do not do well. Failure of anti-hyperuricemic therapy to attain the target urate level is usually due to improper prescribing or poor compliance.¹⁸⁰ Compliance is often a problem when treating chronic asymptomatic conditions, and associated alcoholism can be a factor. Perhaps more important is the fact that patients may need to take up to three different medications on three different schedules to control their symptoms and treat the disease.

It is believed that if patients understand why they are taking medications, they are more likely to be compliant. Toward this end, an analogy has been developed that helps some patients become more compliant.²⁰⁹ In this analogy, urate crystals are compared with matches. The patient is told that “when the match strikes,” it causes a gout attack. To “put out the fire,” the patient takes an NSAID or colchicine. Although this resolves the attack, “the matches are still there.” To eliminate future attacks, the patient is given prophylactic colchicine, “which makes the matches damp and harder to strike,” and allopurinol (or a uricosuric agent), “which actually removes the matches from the body.”

MANAGEMENT OF GOUT AFTER ORGAN TRANSPLANTATION

The management of patients with gout after organ transplantation requires careful consideration. The use of glucocorticoids, azathioprine, or cyclosporine and the precarious status of renal function in many patients pose complex problems. Colchicine and NSAIDs may be inappropriate for the management of acute gouty arthritis in this setting because of their potential toxicities. Intra-articular glucocorticoid injections may be most helpful, and one may be forced to rely more heavily on pain medications in this setting. Prophylactic colchicine can be used in patients with normal renal function, but treatment must be monitored closely. The combination of colchicine and cyclosporine has induced rhabdomyolysis.¹⁷³

When considering chronic therapy, it is helpful to lower the doses of cyclosporine and eliminate the use of diuretics, if possible. Uricosuric agents can be used safely, but their usefulness declines if renal function is poor. Allopurinol can be used in patients with abnormal renal function, but the dose may need to be reduced. Febuxostat may be safer in this setting but has not been studied. But both allopurinol and febuxostat may have severe interactions with azathioprine. Azathioprine is metabolized by xanthine oxidase, and because these drugs inhibit that enzyme, the breakdown of azathioprine is slowed, increasing the effective dose. If care is not taken, significant bone marrow toxicity can result. Thiopurine S-methyltransferase (TPMT) studies should be obtained before starting azathioprine. When azathioprine and allopurinol are used together, they can be started at 25

and 50 mg/day, respectively.²¹⁰ Revised dosing for febuxostat in such a situation has not been determined. Complete blood counts and serum urate level concentrations are then monitored weekly when using allopurinol, and the dose is adjusted to bring the serum urate concentration to less than 6 mg/dL. As an alternative to azathioprine, mycophenolate mofetil has been used effectively with allopurinol in some transplant patients.²¹¹

Uricase has been used to drastically lower serum urate levels and shrink tophi in a small number of patients with gout after cardiac transplantation.²¹² This treatment has been associated with significant allergic reactions including anaphylaxis, bronchospasm, and hemolytic anemia. The newer preparations of uricase such as pegloticase may avoid those complications and prove more effective.²¹³

ANCILLARY FACTORS

In addition to anti-inflammatory agents, colchicine prophylaxis, and antihyperuricemic therapy, other factors may be decisive in determining whether the following develop: recurrent attacks, chronic gouty arthritis, kidney stones, or nephropathy. Today, dietary purine restriction solely to control serum urate levels is rarely advised. A totally purine-free diet reduces the urinary excretion of uric acid by only 200 to 400 mg/day and lowers the mean serum urate value by about 1 mg/dL. In addition, the antihyperuricemic agents available today are so effective that this type of dietary manipulation is rarely necessary. Nevertheless, beneficial results have been reported with a diet of moderate calorie and carbohydrate restriction and a proportionally increased intake of protein and unsaturated fat.²¹⁴ Some subjects with gout are susceptible to acute attacks after the consumption of alcoholic beverages or rich foods. Others describe idiosyncratic responses such as acute gout after eating a particular food, but such relationships are rare and questionable. A diet designed to avoid indiscretions known to precipitate acute gouty attacks in a particular individual is recommended.

In addition, diet is important with regard to other medical problems.²¹⁵ Many gouty patients are overweight, and restoration of ideal body weight through regulated calorie restriction is recommended. In addition, at least 75% of patients with primary gout have hypertriglyceridemia. The initial step in managing hypertriglyceridemia is reduction to ideal body weight and elimination of alcohol ingestion.

Many patients with gout consume liberal amounts of alcohol. Acute excesses may lead to exacerbations of hyperuricemia secondary to temporary hyperlactacidemia, and chronic ingestion of alcohol may stimulate increased purine production.¹⁰⁶ The added purine load resulting from regular ingestion of beer may also be a contributing factor. Patients should be warned about the deleterious effects of excessive alcohol intake. Compliance with medication is also much worse among patients who consume alcohol.

About one-third of gouty subjects are hypertensive. The complications of hypertension are potentially more serious than those of hyperuricemia, and the clinician should not hesitate to use whatever drugs are necessary to control the hypertension. Many hypertensive gouty patients require a

thiazide diuretic. If this medication is necessary to control hypertension, it should be used, with the recognition that the dosage of concomitant antihyperuricemic therapy may need to be adjusted to maintain appropriate control of serum urate levels.

KEY POINTS

Dysregulated chondrocyte differentiation to hypertrophy and inorganic pyrophosphate (PP_i) metabolism are central in pathogenesis of calcium pyrophosphate dihydrate (CPPD) crystal deposition disease.

Autosomal dominant familial CPPD crystal deposition disease has been linked in multiple kindreds to certain mutations in *ANKH*, a gene encoding a PP_i transporter.

NLRP3 (cryopyrin) inflammasome activation and consequent caspase-1 activation and interleukin (IL)-1 β processing and secretion drive cell responses to CPPD crystals and CPPD crystal-induced inflammation.

Degenerative arthropathy caused by CPPD crystal deposition disease often involves joints uncommonly affected by primary osteoarthritis such as the metacarpophalangeal, wrist, and elbow joints.

Diagnosis of CPPD deposition disease before age 55, particularly if CPPD deposition is polyarticular, should prompt differential diagnostic consideration of a primary metabolic or familial disorder, and hyperparathyroidism should always be considered in CPPD deposition disease presenting in patients older than the age of 55.

High-resolution ultrasound appears particularly helpful in diagnosis of CPPD crystal deposition disease, partly because radiographic chondrocalcinosis is not detectable in all joints affected by the disease.

Basic calcium phosphate (BCP) crystal deposition in articular cartilage is intimately linked with osteoarthritis, particularly with osteoarthritis of increased severity.

BCP crystals (unlike urate and CPPD crystals) do not demonstrate birefringence, and specialized methods are required to conclusively identify BCP crystals in specimens from the joint.

ACR AND EULAR CRITERIA FOR DISEASE

Table 96-1 features proposed diagnostic criteria for calcium pyrophosphate dihydrate (CPPD) deposition disease, adapted by the author from the proposed European League Against Rheumatism (EULAR) criteria¹ and the original criteria proposed in the past by Daniel J McCarty and colleagues. The diagnosis is based on detection of CPPD crystals by one or more methods. These include not only standard clinically applied radiography but also high-resolution ultrasound to detect hyaline articular cartilage or fibrocartilage calcifications characteristic of CPPD crystal deposition (termed *chondrocalcinosis*). However, identification of CPPD crystals via compensated polarized light

Calcium Crystal Disease: Calcium Pyrophosphate Dihydrate and Basic Calcium Phosphate ^a

ROBERT TERKELTAUB

microscopic analysis of synovial fluid in the absence of joint infection or other cause of arthritis is the gold standard for diagnosis of CPPD crystal deposition disease, particularly for acute CPPD crystal-associated arthritis (termed *pseudogout*). Detection of typical CPPD crystals in tissue sections also can be accomplished whether specimens are fixed in formaldehyde or ethanol, unlike the case for monosodium urate crystals (which dissolve in formaldehyde). On occasion, specialized crystal analytic approaches including x-ray energy spectroscopy and powder diffraction analysis or atomic force microscopy may be helpful in establishing or confirming CPPD crystal deposition. In assessing the form of deposited crystals in calcifications, determination of the calcium/phosphate ratios and the spacing of x-ray powder diffraction lines provide the most specific information.

Consensus clinical diagnostic criteria for articular basic calcium phosphate (BCP) crystal deposition disorders are not in place. Importantly, BCP crystals (unlike urate and CPPD) do not demonstrate global birefringence, though the aggregated particles of basic calcium phosphate crystals demonstrate edge birefringence. Hence diagnosis is predicated on detection of (1) radiographic detection of calcifications characteristic of BCP crystals, (2) synovial fluid crystals that stain strongly for the calcium-binding dye Alizarin red S (which only weakly stains CPPD crystals), (3) BCP crystals confirmed by transmission electron microscopy or specialized crystal analytic approaches (including those mentioned earlier for CPPD and discussed later).

EPIDEMIOLOGY

KEY POINTS

The true prevalence of both CPPD crystal deposition disease and pathologic articular BCP crystal deposition is not known due to limits of radiographic detection.

Chondrocalcinosis including asymptomatic disease increases progressively in prevalence with aging.

Idiopathic/sporadic chondrocalcinosis is rare before age 55, particularly in the absence of a history of joint trauma or knee meniscectomy.

In the past, studies of the prevalence of both CPPD crystal deposition disease²⁻⁵ and various forms of articular BCP crystal deposition disease have been predominantly based on characteristic plain radiographic features of the disease

Table 96-1 Proposed Diagnostic Criteria for Calcium Pyrophosphate Dihydrate (CPPD) Crystal Deposition Disease

Criteria	
I.	Demonstration of CPPD crystals, obtained by biopsy or aspirated synovial fluid, by definitive means (such as characteristic x-ray diffraction powder pattern)
II.	<p>A. Identification of monoclinic or triclinic crystals showing a weak positive birefringence (or no birefringence) by compensated polarized light microscopy</p> <p>B. Presence of typical calcifications on radiographs (as discussed in text): heavy punctate and linear calcifications in fibrocartilages, articular (hyaline) cartilages, and joint capsules, especially if bilaterally symmetric</p> <p>C. Presence of typical findings for CPPD crystal deposition in articular hyaline cartilage or fibrocartilage by high-resolution ultrasound</p>
III.	<p>A. Acute arthritis, especially of knees, wrists, or other large joints</p> <p>B. Chronic arthritis, especially of knee, hip, wrist, carpus, elbow shoulder, and metacarpophalangeal joints, particularly if accompanied by acute exacerbations</p>
Diagnostic Categories	
A.	Definite: criteria I or IIA must be fulfilled
B.	Probable: criteria IIA or IIB or IIC must be fulfilled
C.	Possible: criteria IIIA or IIIB suggests possible underlying CPPD deposition disease

Modified from McCarty DJ: Crystals and arthritis, *Dis Month* 6:255, 1994.

in limited numbers of joints. This is an incompletely sensitive and specific approach.² Other studies have been based on results of synovial fluid analyses, but definitive studies based on pathologic findings on examination of articular cartilages, or imaging approaches superior to plain radiography, have not been done. As such, the true prevalence of both CPPD crystal deposition disease and pathologic articular BCP crystal deposition is not known.

It is clear that chondrocalcinosis including asymptomatic disease increases progressively in prevalence with aging.²⁻⁵ Idiopathic/sporadic chondrocalcinosis is rare before age 55, particularly in the absence of a history of joint trauma or knee meniscectomy. Studies of prevalence based on radiographs have estimated higher prevalence of chondrocalcinosis when the hands, wrists, pelvis, and knees have been surveyed. Indeed, most elderly patients with chondrocalcinosis of the knee also have detectable chondrocalcinosis in other joints. Knee meniscal fibrocartilage calcification alone has been detected in 16% of women aged 80 to 89 and in 30% of women older than 89,⁶ figures comparable with those obtained in other studies.⁷ In a radiographic survey study of hands, wrists, pelvis, and knees of patients admitted to a geriatrics ward, there was a 44% prevalence of chondrocalcinosis in patients older than 84, a 36% prevalence in the 75- to 84-year-olds, and a prevalence of 15% in 65- to 74-year-olds⁸; studies of U.K. and Italian community cohorts have been limited to analyses of fewer regions (the knee, or knee and pelvis, respectively) and have yielded lower numbers for prevalence.²⁻⁵

In a large U.K. community study the age-, sex-, and knee pain-adjusted prevalence of knee chondrocalcinosis was 4.5% for those older than age 40.³ In some studies, women have appeared somewhat more commonly affected by CPPD crystal deposition disease than men,¹ but in the recent U.K.

study, there was no sex predisposition, although strong association between osteoarthritis (OA) and chondrocalcinosis was confirmed.³ This appeared to be linked more to the presence of osteophytes rather than joint space narrowing with OA. Interestingly, an association between chondrocalcinosis and diuretic use was uncovered, proposed to be due to the capacity of diuretics to induce hypomagnesemia.³

CPPD crystal deposition disease is not uniform in epidemiology between populations. In a random sample of Beijing residents older than 60 years of age, radiographic chondrocalcinosis was compared with whites in the American Framingham OA Study.⁹ Chinese had a much lower prevalence of knee chondrocalcinosis, and wrist chondrocalcinosis was particularly rare in Chinese elderly.⁹ These findings were unexpected because there is an excess of knee OA in Beijing, and chondrocalcinosis and OA are quite commonly associated in the knee joint.

GENETICS

KEY POINTS

The vast majority of CPPD crystal deposition disease is idiopathic/sporadic, but early-onset familial disease also occurs.

Linkage of familial CPPD crystal deposition disease to the gene *ANKH* on chromosome 5p (which encodes a transmembrane protein with functions including PP_i transport) is well established.

The vast majority of CPPD crystal deposition disease is idiopathic/sporadic, but early-onset (defined as onset before age 55) familial disease also occurs.¹⁰ Two major chromosomal linkages, 8q and 5p, have been identified in studies of familial CPPD deposition disease. Linkage with chromosome 8q of both early-onset OA and chondrocalcinosis was given the designation CCAL1, but chromosome 5p-linked chondrocalcinosis (CCAL2) is broadly distributed and has been studied in greater detail than 8q chondrocalcinosis.¹⁰⁻¹² Linkage of familial CPPD crystal deposition disease to the gene *ANKH* on chromosome 5p (which encodes a transmembrane protein with inorganic pyrophosphate [PP_i] transport and other apparent functions discussed later) has been established in these studies.¹⁰⁻¹² A search for *ANKH* mutation in 95 subjects with sporadic chondrocalcinosis uncovered a unique mutation (ΔE590) in one subject.¹¹ Homozygosity for a single nucleotide substitution (−4 G to A) in the *ANKH* 5′-untranslated region that promotes increased *ANKH* messenger RNA expression was present in approximately 4% of British subjects previously thought to have idiopathic/sporadic chondrocalcinosis of aging.¹³

Familial chondrocalcinosis is heterogeneous, and, as one example, prominent CPPD and hydroxyapatite (HA) crystal deposits and cartilage and periarticular calcifications in association with OA were described in a kindred not yet linked to a specific chromosomal locus.¹⁴ A syndrome of spondyloepiphyseal dysplasia tarda, brachydactyly, precocious OA, and intra-articular calcifications with CPPD and/or HA crystals, as well as periarticular calcifications, was linked to mutation of the procollagen type II gene in

indigenous natives of the Chiloe Island region of Chile.¹⁵ This population has a high prevalence of familial CPPD deposition disease. Families affected with diffuse idiopathic skeletal hyperostosis (DISH) and/or chondrocalcinosis have been identified in the Azores Islands, possibly reflecting an unidentified, shared pathogenic mechanism.¹⁶

PATHOGENESIS

KEY POINTS

The loose avascular connective tissue matrices of articular hyaline cartilage, fibrocartilaginous menisci, and of certain ligaments and tendons are particularly susceptible to pathologic calcification.

Joint cartilage pathologic calcification reflects complex interplay between organic and inorganic biochemistry of P_i and PP_i metabolism, aging, dysregulated chondrocyte growth factor responsiveness and differentiation, and other factors.

The loose avascular connective tissue matrices of articular hyaline cartilage, fibrocartilaginous menisci, and of certain ligaments and tendons are particularly susceptible to calcification. Calcium-containing crystals deposited in the pericellular matrix of cartilage are often in the form of CPPD (chemical formula, $Ca_2P_2O_7 \cdot H_2O$; calcium-to-phosphate ratio, 1). Crystals of BCP including partially carbonate-substituted HA ($Ca_5[PO_4]_3OH \cdot 2H_2O$; calcium-to-phosphate ratio, 1.67) also may be deposited pathologically in articular cartilage, particularly in OA. Importantly, physiologic (and noninflammatory) deposition of HA is essential because HA is the principal mineral phase laid down in growth cartilage and in bone.

Inflammatory conditions also may result from deposition of HA, as well as the closely related BCP crystals, octacalcium phosphate (OCP) ($Ca_8H_2[PO_4]_6 \cdot 5H_2O$; calcium-to-phosphate ratio, 1.33) and tricalcium phosphate or “whitlockite” ($Ca_3[PO_4]_2$; calcium-to-phosphate ratio, 1.5) in periarticular structures such as the rotator cuff (calcific tendinitis) and subacromial bursa of the shoulder (see Chapter 46). CPPD and BCP crystal deposition, reviewed here, are by far the most prevalent arthropathies associated with calcium-containing crystals. Articular calcium oxalate crystal deposition is less common.

Articular cartilage, unlike growth plate cartilage, is specialized to avoid the process of matrix calcification. However, the matrix of articular hyaline cartilage, like that of fibrocartilaginous menisci, lends itself well to pathologic calcification,¹⁷ particularly in association with certain changes in extracellular matrix composition and hydration in aging and OA.¹⁸ Joint cartilage calcification reflects complex interplay between organic and inorganic biochemistry, ion transport, aging, genetics, inflammation, oxidative stress, and dysregulated chondrocyte growth factor responsiveness and differentiation. Pathologic cartilage calcification can reflect deficiencies of certain physiologic calcification inhibitors or upregulation of mediators that actively drive certain patterns of tissue injury culminating in calcification within degenerating cartilage.^{19,20}

Alteration of the concentrations of calcium, inorganic phosphate (P_i), PP_i , and the solubility products of these

ions are clearly at work in promoting CPPD and BCP crystal formation.¹⁹ The levels of ambient magnesium and the composition of the chondrocyte extracellular matrix influence the dynamics of CPPD crystal formation and help to determine whether predominantly monoclinic or triclinic CPPD crystals are predominantly formed.^{21,22} Significantly, monoclinic CPPD crystals are more inflammatory than triclinic CPPD crystals.²³ Matrix effects for CPPD and BCP crystals, studied in experimental gel systems, include promotion of CPPD formation by adenosine triphosphate (ATP) and corticosteroids in conjunction with matrix type I collagen and osteopontin, whereas type II collagen and intact proteoglycans appear to suppress ATP-driven CPPD crystal formation in vitro.^{21,22} Experimental systems to analyze CPPD and BCP crystal deposition have commonly employed isolated matrix vesicle cell fragments from chondrocytes that are enriched in prominerizing constituents and provide a nidus for initiation of calcification, specifically with BCP crystals.²¹ Matrix vesicles are important in cartilage growth plate calcification, but it is not yet clear whether CPPD and BCP crystal formation in articular cartilages is driven more by matrix vesicle-mediated effects or nucleation of crystals in association with changes in extracellular matrix constituents, or both pathways. However, CPPD crystals are too large (micron size) to form within matrix vesicles. It should be noted that loci of pericellular concentration of PP_i may be necessary to drive CPPD crystal formation at low micromolar PP_i concentrations developing in cartilages with chondrocalcinosis.

Besides physical effects of calcium, P_i , and PP_i on crystal nucleation and propagation, these same solutes exert a variety of mineralization-regulating effects on gene expression, differentiation, and viability in chondrocytes, mediated partly by calcium-sensing receptors and sodium-dependent inorganic phosphate co-transport in chondrocytes.^{24,27} Noxious effects of excess PP_i on chondrocytes including induction of matrix metalloproteinase-13 (MMP-13) expression²⁸ and promotion of apoptosis²⁹ support the clinical terminology *pyrophosphate arthropathy* to describe chronic cartilage degenerative manifestations of CPPD crystal deposition disease.

Dysregulated Inorganic Pyrophosphate Metabolism in Pathologic Articular Cartilage Calcification

PP_i is a potent inhibitor of the nucleation and propagation of BCP crystals.¹⁹ Concordantly, maintenance of physiologic extracellular PP_i levels by chondrocytes and certain other cells serves to suppress calcification with HA, as illustrated in mouse models of deficient PP_i generation and transport,²⁵ and a variant of human infantile arterial calcification associated with periarticular calcification.³⁰ The relatively unique capacity of chondrocytes to produce copious amounts of extracellular PP_i is double-edged (Figure 96-1), as supersaturation of cartilage extracellular matrix with PP_i is a major factor in promoting CPPD crystal deposition.^{19,31,32} Furthermore, excess PP_i generation can promote BCP crystal deposition by providing a source for increased extracellular P_i generation via PP_i hydrolysis by the ectoenzyme tissue-nonspecific alkaline phosphatase (TNAP)^{19,25} (see Figure 96-1). Depending on cartilage ATP and PP_i

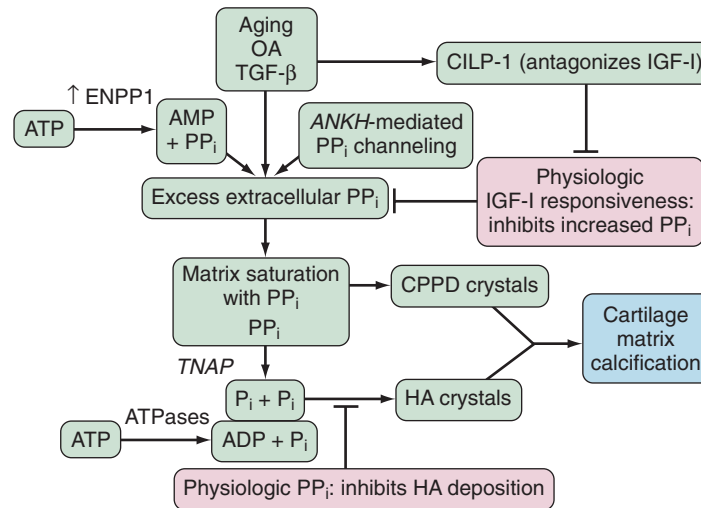

Figure 96-1 Proposed inorganic pyrophosphate (PP_i)-dependent mechanisms stimulating calcium pyrophosphate dihydrate (CPPD) and hydroxyapatite (HA) crystal deposition in aging and osteoarthritis (OA). Roles of adenosine triphosphate (ATP) and PP_i metabolism and inorganic phosphate (P_i) generation in pathologic cartilage calcification. This model accounts for the association of extracellular PP_i excess with both CPPD and basic calcium phosphate (HA) crystal deposition in OA and chondrocalcinosis, as well as the paradoxical association of extracellular PP_i deficiency (from defective ANKH or ectonucleotide pyrophosphatase/phosphodiesterase 1 [ENPP1] expression) with pathologic calcification of articular cartilage with HA crystals in vivo. Factors driving pathologic calcification are indicated in green and physiologic factors suppressing calcification in red. Excess PP_i generation in aging cartilages in idiopathic CPPD deposition disease of aging and in OA cartilages is mediated in part by increased ENPP1. In idiopathic chondrocalcinosis of aging, mean cartilage PP_i and nucleotide pyrophosphatase phosphodiesterase (NPP) catalytic activity levels are double normal. ENPP1 is markedly increased at sites of meniscal cartilage calcification in vivo, and NPP1 directly induces PP_i elevation and matrix calcification by chondrocytes in vitro. Depending on extracellular availability of substrate PP_i and the activity of the pyrophosphatase tissue-nonspecific alkaline phosphatase (TNAP), the availability of substrate ATP and the activity of ATPases, as well as other factors such as substantial local Mg²⁺ concentrations and HA crystal deposition, as opposed to CPPD deposition, may be stimulated. In this model, excess extracellular PP_i also may result from heightened “leakiness” of intracellular PP_i via increased ANKH expression in OA and abnormal ANKH function in familial chondrocalcinosis. Also illustrated is the role in cartilage calcification in OA and aging of increased expression of cartilage intermediate layer protein-1 (CILP-1), which inhibits the capacity of insulin-like growth factor-I (IGF-I) to suppress elevation of extracellular PP_i. AMP, adenosine monophosphate; TGF-β, transforming growth factor-beta.

concentrations, as well as the level of activity of P_i-generating ATPases and TNAP, CPPD and HA crystal formation may be jointly promoted in cartilage, an event that commonly occurs clinically in OA.

Role of ENPP1 and ANKH in Inorganic Pyrophosphate Metabolism in Chondrocalcinosis

Sporadic aging-associated CPPD crystal deposition disease is consistently linked with excess chondrocyte PP_i-generating nucleotide pyrophosphatase phosphodiesterase (NPP) activity and augmented PP_i generation by chondrocytes.^{19,31,32} In this context, the NPP family isoenzymes ectonucleotide pyrophosphatase/phosphodiesterase 1 (ENPP1) (formerly known as NPP1 and *plasma cell membrane glycoprotein-1* [PC-1]) and ENPP3 (formerly known as B10) actively generate PP_i by hydrolysis of nucleoside triphosphates including ATP.^{19,31,32} ENPP1 plays a central role in sustaining and augmenting extracellular PP_i in chondrocytes and certain other cells (see Figure 96-1). A substantial portion of ATP used by chondrocytes to generate extracellular PP_i is provided by the mitochondria.¹⁹

ENPP1 is one of a family of enzymes that share NPP catalytic activity and modular type II transmembrane ectoenzyme structures.^{19,33} ENPP1 plays by far the greatest role in augmenting extracellular PP_i in chondrocytes.^{31,32} Significantly, marked and total ENPP1 deficiency states in vivo and in vitro are associated with up to 50% less plasma and extracellular PP_i.^{24,30} In contrast, in idiopathic

chondrocalcinosis, cartilage NPP activity and PP_i levels may average approximately double those of normal subjects.³⁴

Increased ENPP1 expression is associated with both calcification and apoptosis in degenerative human cartilages.³¹ In more advanced osteoarthritis, decreased cartilage ENPP1 has been described and promotes BCP crystal deposition.^{34a} Direct upregulation of ENPP1 in chondrocytic cells stimulates calcification, as well as apoptosis.³⁵ These effects are not shared by ENPP3, which likely has other intracellular “housekeeping” functions in chondrocytes.³¹ ENPP2, which is also expressed in normal cartilages, functions more actively in physiology as a lysophospholipase D, and ENPP2 only modestly stimulates chondrocytes to calcify in vitro.³¹

ANKH encodes a multiple-pass transmembrane protein that functions in PP_i channeling³⁶⁻³⁹ (Figure 96-2) and possibly ATP release⁴⁰ and regulation of P_i metabolism and uptake by the type III sodium-dependent P_i co-transporter Pit-1.⁴¹ ANKH promotes bidirectional movement of PP_i at the plasma membrane in vitro,³⁸ but the gradient for ANKH-stimulated PP_i movement in chondrocytes (which generate abundant PP_i both by their robust ENPP1 expression and intense matrix biosynthetic activity) is from the intracellular to the extracellular space.¹⁹ Indeed, ANKH transport of PP_i generated intracellularly by ENPP1²⁸ may be the primary means to regulate extracellular PP_i levels.¹⁹ Modeling of the PP_i channeling function of ANKH has proposed 10 or 12 membrane-spanning domains in ANKH with an alternating inside/out orientation and with a central channel to accommodate the passage of PP_i.^{36,38} (see Figure 96-2).

Figure 96-2 Model for multiple-pass membrane protein structure of ANKH and for ANKH mutations associated with chromosome 5p-linked autosomal dominant familial chondrocalcinosis and heritable late-onset chondrocalcinosis. The figure schematizes the putative multiple-pass transmembrane protein structure of ANKH, which appears to promote bidirectional inorganic pyrophosphate (PP_i) movement between the cytosol to the extracellular space. The gradient for ANKH-stimulated PP_i movement in chondrocytes (which generate abundant PP_i both by high specific activity of ectonucleotide pyrophosphatase/phosphodiesterase 1 and robust matrix biosynthesis) is from the intracellular to the extracellular space. Distinct mutations in ANKH promote differences in age of onset and phenotypes in familial chondrocalcinosis. The figure summarizes sites of known ANKH mutations clustered near the N-terminus that are associated with chromosome 5p-linked autosomal dominant familial chondrocalcinosis (calcium pyrophosphate dihydrate [CPPD] crystal deposition disease), and all, except the French kindred M48T (which increases intracellular PP_i and disrupts the association of ANKH with the inorganic phosphate transporter Pit-1), may act in part by increasing extracellular PP_i. A C-terminal domain ANKH mutation ΔE590 linked with one case of sporadic chondrocalcinosis is not depicted; ANKHΔE590 appears to indirectly suppress PP_i catabolism by association with impairing tissue-nonspecific alkaline phosphatase expression. The figure also depicts the -4 G to A transition in the 5'-untranslated region of ANKH for which homozygosity is seen in approximately 4% of late-onset chondrocalcinosis of the sporadic type, suggesting a heritable subset of otherwise typical late-onset chondrocalcinosis. As a group, the N-terminally clustered ANKH mutations linked to human chondrocalcinosis promote chronic low-grade extracellular PP_i excess resulting in CPPD crystal formation.

ANKH is clearly implicated in the pathogenesis of familial and idiopathic/sporadic chondrocalcinosis,^{10,13} and increased ANKH expression in cartilage is a factor in secondary chondrocalcinosis in OA²⁸ (see Figure 96-1). In this context, expression of wild-type ANKH is highly regulated and ANKH is increased in OA and chondrocalcinotic cartilages.²⁸ Interestingly, hypoxia, via effects of the transcription factor hypoxia inducible factor-1α, suppresses ANKH expression.⁴² It is conceivable that increased permeability to oxygen of fibrillated and fissured cartilage in OA favors increased ANKH expression. ANKH, in conjunction with signaling via extracellular P_i likely derived from PP_i, promotes chondrocyte maturation to the procalcifying hypertrophic differentiation state.⁴³ Figure 96-1 presents a model in which secondary alterations in chondrocyte expression of both wild-type ANKH and ENPP1 drive PP_i supersaturation in cartilage in idiopathic/sporadic and OA-associated CPPD crystal deposition disease.

Mutations at different locations in ANKH can affect function and the skeleton in a manner including autosomal dominant chondrocalcinosis^{10,37-39} and certain other

phenotypes. These include murine progressive ankylosis in the *ank/ank* mouse and human craniometaphyseal dysplasia associated with apparent decrease of the capacity to transport PP_i within bone and effects on bone resorption and remodeling, putatively mediated in part by direct and indirect effects on osteoclasts.^{36,39,44} In a consanguineous family with mental retardation, deafness, and ankylosis, with painful small joint soft tissue calcifications, progressive spondyloarthropathy, osteopenia, and mild hypophosphatemia, the homozygous ANK missense mutation L244S was detected in all patients.⁴⁵ The mutant ANK protein was expressed and localized to the plasma membrane, but fibrosis and mineralization of articular soft tissues developed in homozygotes, with heterozygous carriers of the L244S mutation showing mild osteoarthritis without metabolic alterations.⁴⁵

Clinical heterogeneity even for chondrocalcinosis associated with ANKH mutations¹⁰ suggests differing functional effects of ANKH mediated by specific regions of the molecule. All the N-terminally clustered ANKH mutations identified to cause familial chondrocalcinosis (see Figure 96-2) appear to increase PP_i transport.³⁸ However, some ANKH mutations have distinct effects on chondrocyte differentiation.¹³ The M48T ANKH mutant in the French kindred appears functionally unique by association with increased intracellular PP_i⁴⁶ and also interrupts the interaction of ANKH with the sodium/phosphate co-transporter Pit-1.⁴⁷ This may be functionally significant because elevated P_i increases both ANKH and Pit-1 expression and because ANKH and Pit-1 co-localize in chondrocytes.⁴⁷ In addition are the P_i effects on chondrocyte differentiation discussed later. In 5p familial chondrocalcinosis, subtle gain of function of intrinsic ANKH PP_i channeling activity may lead to chronic, low-grade chondrocyte “PP_i leakiness,” thereby causing matrix supersaturation with PP_i, CPPD crystal deposition, and cartilage degeneration.^{10,37,48} An alternative mechanism of disrupting PP_i metabolism may be promoted by the ANKH mutation ΔE590 linked with a case of sporadic chondrocalcinosis¹¹ because ANKHΔE590 appears to indirectly suppress PP_i catabolism by association with impairing TNAP expression.⁴⁹

Effects of Imbalance of Chondrocyte Growth Factor Responses on Inorganic Pyrophosphate Metabolism in Chondrocalcinosis

The chondrocyte growth factor transforming growth factor (TGF)-β stimulates ATP release by chondrocytes,⁴⁰ as well as ENPP1 expression and ENPP1 subcellular movement to the plasma membrane, which drive elevation of extracellular PP_i.^{32,50} Interleukin (IL)-1β suppresses both ENPP1 expression and extracellular PP_i in chondrocytes and blocks the effects of TGF-β on PP_i.^{32,50} The capacity of TGF-β to raise chondrocyte PP_i rises with aging, as does TGF-β-stimulated NPP activity,⁵¹ whereas growth-promoting effects of TGF-β decrease with aging in articular chondrocytes.⁵² The anabolic chondrocyte growth factor insulin-like growth factor-I (IGF-I) normally suppresses extracellular PP_i (as well as ATP release)⁴⁰ in chondrocytes⁵³ (see Figure 96-1). Moreover, chondrocyte IGF-I resistance is characteristic of OA and aging cartilages⁵⁴ (see Figure 96-1). IGF-I induces expression of cartilage intermediate layer protein (CILP)

(see Figure 96-1), a secreted cartilage matrix molecule. CILP's expression rises in aging and OA and is most abundant in the middle zone of articular cartilage where CPPD crystal deposition is most prevalent. Significantly, the CILP-1, but not the CILP-2 isoform, promotes increased extracellular PP_i in chondrocytes indirectly by antagonizing IGF-I at the receptor level.⁵⁴

CPPD Deposition Disease Secondary to Primary Metabolic Disorders: Relationship to Inorganic Pyrophosphate Metabolism and Chondrocyte Differentiation

Hypophosphatasia, hypomagnesemic conditions (including the Gitelman's variant of Bartter's syndrome), hemochromatosis, and hyperparathyroidism are the best-characterized primary metabolic disorders linked to secondary CPPD crystal deposition disease.⁵⁵ Increased joint fluid PP_i levels in each of these conditions suggests at least one common thread in the pathogenesis of chondrocalcinosis via cartilage PP_i excess.⁵⁶ Magnesium is a cofactor for pyrophosphatase activity, and iron excess can suppress pyrophosphatase activity. Hypercalcemia may promote CPPD crystal deposition in hyperparathyroidism (and in familial hypocalciuric hypercalcemia)⁵⁷ by effects beyond cartilage matrix supersaturation with ionized calcium such as calcium function as a cofactor in ENPP1 catalytic activity, as well as chondrocyte-activating effects mediated by the calcium-sensing receptor.²⁷ In addition, normal articular chondrocytes express parathyroid hormone/parathyroid-hormone-related protein (PTH/PTHrP) receptors, and functional responses of chondrocytes to PTH can promote proliferation, altered matrix synthesis, and mineralization.^{58,59}

Hypophosphatasia is due to deficient activity of TNAP, consequently with effects including limitation of hydrolysis PP_i to generate P_i .²⁵ TNAP is a major physiologic antagonist of ENPP1-mediated elevation of extracellular PP_i .²⁵ Conversely, physiologic ENPP1-induced PP_i generation antagonizes the essential prominerallizing effects of TNAP mediated by P_i generation,²⁵ and cartilage PP_i excess presumably drives chondrocalcinosis in hypophosphatasia. *Enpp1* knockout mice and mice homozygous for the ENPP1 truncation mutant *ttw* demonstrate marked articular cartilage calcification with HA and OA, as well as ankylosing spinal ligament hyperostosis and synovial joint ossific fusion; extracellular PP_i levels and mineralization disturbances in soft tissues (but not long bones) of *Enpp1* knockout and TNAP-deficient mice are mutually corrected by cross-breeding.²⁵

Inflammation, Hypertrophic Chondrocyte Differentiation, and Transglutaminase 2 in Joint Cartilage Calcification

Regulated changes in chondrocyte differentiation and viability appear to be a mechanistically unified process that promotes joint cartilage HA and CPPD crystal deposition, as well as OA.⁶⁰ Such changes include development of foci of chondrocyte maturation to hypertrophy,⁶⁰ with the presence of hypertrophy, as seen in histopathology of the knee cartilage in Figure 96-3, and apoptosis of chondrocytes typically found adjacent to cartilage calcifications.^{61,62} Articular

Figure 96-3 Calcium pyrophosphate dihydrate (CPPD) crystal deposition arthropathy of the knee joint. **A**, Femoral condyle. There are extensive foci of chalky white particulate deposits within the articular cartilage. This is characteristic of CPPD crystal deposition. **B**, Histology of CPPD crystal deposition within the hyaline articular cartilage. The hypertrophic chondrocytes adjacent to the crystal aggregates are within enlarged chondrons (hematoxylin and eosin, original magnification $\times 250$). **C**, Polarized light microscopy of CPPD crystal aggregates within the hyaline articular cartilage. The individual crystals have rod and rhomboid shapes and are positively birefringent (original magnification $\times 250$). (Courtesy Dr. Ken Pritzker, Mount Sinai Hospital Pathology Department, University of Toronto, Ontario, Canada.)

chondrocyte hypertrophy⁶⁰ is associated with heightened PP_i generation; increased production of calcifying, membrane-limited cell fragments known as matrix vesicles⁶³; and certain other calcification-promoting changes in differentiation including alteration of extracellular matrix composition, such that osteopontin (which promotes CPPD crystal formation) is increased and normal collagen subtype composition in the matrix is lost.⁶⁴ Altered TGF- β signal transduction in aging and OA may be involved in promoting chondrocyte hypertrophy.⁶⁵

P_i taken up by Pit-1 sodium-dependent co-transport and calcium sensing can modulate chondrocyte hypertrophic differentiation and apoptosis, as well as PP_i -modulating responses to TGF- β .^{19,31,66-69} Local upregulation of PTHrP expression also may be one of the shared features driving sequential chondrocyte proliferation and altered differentiation in growth plate chondrocytes and articular chondrocytes.²⁷ Chondrocyte apoptosis also promotes calcification partly through the calcifying potential of apoptotic bodies functioning as “inside-out” matrix vesicles on release from dying chondrocytes.⁷⁰⁻⁷² Mitochondrial dysfunction, a central factor in tissue aging and an apparent mediator of OA progression in aging,^{73,74} also can stimulate cartilage matrix degeneration and calcification. Mitochondria are remarkably specialized to regulate calcification, and apoptosis is critically regulated by mitochondrial function. Moreover, chondrocyte ATP depletion is driven via suppression of mitochondrial oxidative phosphorylation by nitric oxide (NO) as OA evolves in aging, thereby promoting increased ATP scavenging by NPP activity and consequent augmentation of extracellular PP_i .⁷⁴

Inflammation-associated chondrocyte hypertrophy is driven by hypoxia-inducible factor-2 α and Indian hedgehog,⁶⁰ as well as by multiple cytokines and calgranulins, oxidative stress, P_i transport, and receptor for advanced glycation end products (RAGE) signaling, and it is modulated by transglutaminase 2 (TG2) release. Chondrocyte hypertrophy and inflammation jointly drive chondrocalcinosis and progression of OA. For example, IL-1 β , which is increased in OA cartilage, stimulates articular chondrocytes to calcify the matrix.^{51,64} NO stimulates both apoptosis and calcification in chondrocytes.⁷¹ IL-1 β stimulates inducible nitric oxide synthase (iNOS) expression and increased NO generation, as well matrix alterations. IL-1 β (as well as TNF, donors of NO, and the potent oxidant peroxynitrite) also induces increased chondrocyte transglutaminase (TG) activity mediated through the TG family enzymes, factor XIIIa and TG2.^{51,64}

TG2 and factor XIIIa, which function in part to cross-link proteins by transamidation, are markers of growth plate chondrocyte hypertrophy.^{51,64} Significantly, there is upregulation of TG2 and factor XIIIa expression in hypertrophic cells in the superficial and deep zones of knee OA articular cartilage and the central (chondrocytic) zone of OA menisci.⁵¹ Moreover, increased factor XIIIa and TG2 activities both directly stimulate calcification by chondrocytes.⁵¹ OA severity-related, donor age-dependent, and marked age-dependent IL-1-induced increases in TG activity occur in chondrocytes from human knee menisci.⁵¹ TG2 is essential for IL-1 β to stimulate articular chondrocytes to calcify in vitro.⁶⁴ In addition, the closely related inflammatory chemokines CXCL1 and CXCL8, which are both increased in OA cartilage, induce TG2⁷⁵ and chondrocyte hypertrophic differentiation and calcification that requires TG2.⁷⁵ Distinct TG2-independent and TG2-dependent mechanisms promote articular chondrocyte hypertrophy and calcification in vitro, and increased TG2 release is sufficient to promote chondrocyte hypertrophy.^{64,76} TG2 also promotes activation of TGF- β .⁷⁷

The multiligand RAGE mediates several chronic degenerative diseases accompanied by low-grade inflammation.⁷⁸ RAGE ligands include S100/calgranulins, a class of small, calcium-binding polypeptides, several of which are expressed by chondrocytes. Normal human knee cartilages demonstrate constitutive RAGE and S100A11 expression, and both RAGE and S100A11 expression are increased in OA cartilages. CXCL8 and TNF induce S100A11 release in cultured chondrocytes.⁷⁸ Furthermore, S100A11 induces chondrocyte hypertrophy in vitro,⁷⁸ and it does so in a manner dependent on S100A11 homodimerization catalyzed by TG2-mediated transamidation and antagonized by the alternative S100A11 receptor CD36.^{79,80} CXCL1-induced and TNF-induced chondrocyte hypertrophy require RAGE signaling.⁷⁸

Special Pathogenic Aspects of Articular and Periarticular Basic Calcium Phosphate Crystal Deposition

CPPD and BCP crystal deposition can develop in different zones of articular cartilage and probably in distinct phases of cartilage degenerative disease such as ongoing loss of viability in hypertrophic chondrocytes. In addition,

abundant cartilage NO production may promote mitochondrial dysfunction, chondrocyte extracellular ATP depletion,⁷⁴ and lowering of extracellular PP_i, consequently favoring HA over CPPD crystal deposition.⁸¹ The observation that OA and HA crystal deposition in articular cartilage (and arteries)³⁰ are both promoted by extracellular PP_i deficiency states strikingly illustrates the deleterious effects of deprivation of physiologic extracellular PP_i levels.¹⁹ Yet it is noted that joint fluid PP_i and NPP activity are elevated in HA-associated shoulder arthropathy (Milwaukee shoulder syndrome [MSS]),⁸² consistent with the model in Figure 96-1.

Pathologic BCP crystal deposition may occur in periarticular sites, as well as numerous organs and soft tissues. Significantly, the shoulder is the most common articular region affected by symptomatic BCP crystal deposition, in part reflecting unique shoulder structure-function (see Chapter 46). Degenerative changes promoted by biomechanical stress promote calcific tendinitis in the body of the rotator cuff.⁸² Such tendon calcifications can remain asymptomatic and also can eventually resorb, but the degenerative changes can predispose to tendon rupture. Osteopontin, a factor that normally restrains BCP crystal deposition (and is regulated by PP_i and P_i),²⁴ can be detected in fibroblast-like cells and multinucleated macrophages surrounding areas of calcification in calcific tendinitis.⁸³ In this regard, osteopontin promotes oxidative stress, MMP activation, and macrophage recruitment and osteoclast activation.²⁴ The presence of multinucleated cells with cathepsin K expression and osteoclast-like functions at sites of tendon calcification⁸⁴ suggests a mechanism for both resorption of BCP crystal deposits and tendon degeneration.

Crystal-Induced Inflammation

Some of the crystals deposited in cartilage (Supplemental Figure 96-1 on www.expertconsult.com) can subclinically traffic to joint fluid and synovium, and the crystals can directly stimulate chondrocytes, synovial lining cells, and intra-articular leukocytes.⁸⁵⁻⁹¹ Inflammation triggered by CPPD and BCP crystals thereby contributes to cartilage degradation and can potentiate worsening of OA.⁸⁵⁻⁹¹ Many proinflammatory mechanisms active in gout also likely mediate synovitis and cartilage degeneration associated with CPPD and BCP crystal deposition.⁸⁵⁻⁹¹ In this regard, CPPD and BCP crystals activate cells partly via nonspecific activation of signal transduction pathways (e.g., mitogen activated protein kinase activation) and induce cellular release of cyclooxygenase- and lipoxygenase-derived metabolites of arachidonic acid and cytokines including tumor necrosis factor (TNF), IL-1, and CXCL8.⁸⁵⁻⁹¹ Innate immune recognition of extracellular CPPD crystals by Toll-like receptor 2 (TLR2)⁹² and CPPD crystal-induced activation of the intracellular NLRP3 (cryopyrin) inflammasome, resulting in caspase-1 activation and IL-1 β processing and release, drive cell responses to CPPD crystals in vitro and CPPD crystal-induced inflammation in vivo.⁹³

The ingress of neutrophils into the joint is central in triggering acute crystal-induced synovitis, and effects on neutrophil-endothelial interaction likely represent a major locus for prophylactic effects of nanomolar concentrations of colchicine for the acute arthritis of pseudogout.⁹⁵ CXCL8

Supplemental Figure 96-1 **A**, Chalky calcium pyrophosphate dihydrate (CPPD) crystal deposits observed on synovium, menisci, and hyaline cartilage of a 35-year-old patient with familial calcium pyrophosphate deposition disease. **B**, Menisci showing black-stained crystalline deposits under von Kossa's stain. **C**, Crystalline pyrophosphate deposits in articular cartilage. (Compensated polarized light, $\times 300$.) **D**, Hypertrophic chondrocytes surrounding CPPD deposits (hematoxylin and eosin, original magnification $\times 400$).

and related chemokines that bind the CXCL8 receptor CXCR2 (including CXCL1) appear to be critical in initiating and perpetuating neutrophil ingress in acute crystal-induced inflammation.⁹⁶ Despite the fact that BCP and CPPD crystals share the capacity to activate certain cell signaling pathways and to induce several MMPs, BCP crystals generally trigger much less neutrophil influx into the joint than do CPPD crystals. Concordantly, free intra-articular BCP crystals likely induce less proinflammatory cytokine expression than do CPPD and monosodium urate crystals,⁹⁷⁻⁹⁹ though OCP crystals could be more inflammatory than hydroxyapatite crystals.¹⁰⁰

CLINICAL FEATURES

KEY POINTS

In the elderly, CPPD deposition can mimic conditions including gout, infectious arthritis, primary osteoarthritis, RA, or polymyalgia rheumatica. It can also present as fever of unknown origin.

Pseudogout is a major cause of acute monoarticular or oligoarticular arthritis in the elderly; attacks typically involve a large joint, most often the knee, and less often the wrist or ankle, and, unlike gout, rarely the first metatarsophalangeal joint.

Chronic degenerative arthropathy in CPPD deposition disease commonly affects certain joints that are typically spared in primary OA (e.g., metacarpophalangeal joints, wrists, elbows, glenohumeral joints).

Calcium Pyrophosphate Dihydrate Deposition Disease

Most elderly individuals with CPPD deposition disease in the United States have a primary (idiopathic/sporadic) disorder (Table 96-2). Idiopathic chondrocalcinosis generally appears only after the fifth decade of life. But patients with a history of repetitive joint trauma of knee meniscectomy

Table 96-2 Causes of Calcium Pyrophosphate Dihydrate Crystal Deposition Disease

High Prevalence
Idiopathic in association with aging (most frequent)
Complication of primary osteoarthritis
Long-term consequence of mechanical joint trauma or knee meniscectomy
Moderate Prevalence
Familial
Associated with systemic metabolic disease (hyperparathyroidism, dialysis-dependent renal failure, hemochromatosis, hypomagnesemia)
Low Prevalence (Largely Based on Case Reports)
X-linked hypophosphatemic rickets
Familial hypocalciuric hypercalcemia
Ochronosis
Gout
Articular amyloidosis
Myxedematous hypothyroidism
Osteochondrodysplasias and spondyloepiphyseal dysplasias
Neuropathic joints
Wilson's disease

Table 96-3 Common Clinical Presentations of Calcium Pyrophosphate Dihydrate (CPPD) Crystal Deposition Disease

Asymptomatic or incidental finding (e.g., asymptomatic knee fibrocartilage chondrocalcinosis in the elderly)
Recurrent acute inflammatory monoarticular arthritis (pseudogout) (e.g., wrist, knee, including provocation by trauma, concurrent medical or surgical illness, or intra-articular hyaluronan)
Pseudoseptic arthritis
Recurrent acute hemarthrosis
Chronic degenerative arthritis (pseudo-osteoarthritis or pseudo-neuropathic arthritis)
Chronic symmetric inflammatory polyarthritis (pseudorheumatoid arthritis)
Systemic illness (pseudo-polymyalgia rheumatica, fever of unknown origin)
Destructive arthritis in dialysis-dependent renal failure
Carpal tunnel syndrome
Tumoral and pseudotumefactive CPPD crystal deposits
Central nervous system disease complicating ligamentum flavum or transverse ligament of atlas involvement (cervical canal stenosis, cervical myelopathy, meningismus, foramen magnum syndrome, odontoid fracture)

may present with nonsystemic (monoarticular) chondrocalcinosis before age 55. Familial forms of CPPD crystal deposition disease also have been widely documented, as discussed later. The clinical presentation of familial chondrocalcinosis is often manifested in the third and fourth decades of life, but familial disease can sometimes be detected before age 20 or first present clinically at advanced age. CPPD crystal deposition disease is also a common manifestation of a variety of hereditary and metabolic conditions (including hyperparathyroidism, dialysis-dependent renal failure, and hemochromatosis)⁵⁵ in which the CPPD-related arthropathy can present earlier than age 55. For unclear reasons, hemochromatosis can present predominantly with CPPD crystal deposition disease or as OA. The weight of evidence from controlled studies suggests that hypothyroidism (with the probable exception of myxedematous hypothyroidism) is not associated with a significantly increased prevalence of CPPD crystal deposition disease, though both disorders are clearly prevalent in aging.^{55,101,102} It has been suggested that initiation of thyroxine supplementation therapy may trigger pseudogout.¹⁰³

The clinical manifestations of CPPD deposition disease vary widely¹⁰⁴ (Table 96-3). Quite commonly, the disease can be asymptomatic. Alternatively, it can mimic OA (pseudo-osteoarthritis), gout (pseudogout) (Supplemental Figure 96-2 on www.expertconsult.com), acute-onset or insidious rheumatoid arthritis (RA) (pseudorheumatoid arthritis) (Figure 96-4), or present as “pseudo-neuropathic” arthropathy. Patients with CPPD crystal deposition disease also commonly present with episodes of hemarthrosis, often post-traumatic and in the knee. The contributions of the forms of CPPD deposited (e.g., monoclinic vs. triclinic crystals) and of host factors to these wide differences in clinical manifestations are not clear. Overall, only a small fraction of patients with CPPD deposition disease have prolonged, recurring polyarticular inflammation. Progressive degenerative arthropathy is more common. Though CPPD deposition disease appears to be a common and significant public health problem in the elderly, the disease and health-related quality of life impact and the long-term course of CPPD-

Supplemental Figure 96-2 **A**, Acute pseudogout. The patients in **A**, **C**, and **D** are siblings. **B**, Pseudo-osteoarthritis. **C**, Pseudo-rheumatoid arthritis with boutonnière deformity. **D**, Pseudo-rheumatoid arthritis showing ulnar deviation, interosseous muscle atrophy, and metacarpophalangeal and wrist joint involvement.

Figure 96-4 Idiopathic symmetric pseudorheumatoid calcium pyrophosphate dihydrate (CPPD) deposition arthropathy in an elderly female. This 84-year-old female presented with a history of past right carpal tunnel syndrome and with chronic symmetric proliferative synovitis of both wrists and second and third metacarpophalangeal (MCP) joints, with physical findings of synovial and dorsal extensor tenosynovial swelling of the wrists and synovial swelling at the second to third MCP joints (**A**). Changes on hand and wrist plain radiographs consistent with the diagnosis of CPPD deposition disease, presented for the right wrist (**B**), included cystic changes in multiple carpal bones including the scaphoid and lunate, linear calcification on the ulnar side of the carpus (arrow) typical for the chondrocalcinosis of CPPD deposition, and mild narrowing of the radiocarpal joint indicative of cartilage loss.

associated degenerative arthropathy in an unselected population have not been adequately evaluated.

Acute Synovitis

Pseudogout is a major cause of acute monoarticular or oligoarticular arthritis in the elderly. The attacks typically involve a large joint, most often the knee and less often the wrist or ankle, and, unlike gout, rarely the first metatarsophalangeal joint. Acute attacks of inflammatory pseudogout in patients with CPPD deposition disease typically have a sudden onset and can be excruciatingly painful, with pronounced periarticular erythema, warmth, and swelling, comparable to gout. In addition, arthritis in some attacks of pseudogout can be migratory or can be additive, polyarticular, and bilateral. Polyarticular pseudogout is particularly common in association with familial chondrocalcinosis and hyperparathyroidism.

Pseudogout can be provoked by minor trauma or intercurrent medical or surgical conditions including pneumonia, myocardial infarction, cerebrovascular accident, and pregnancy. Parathyroid surgery for hyperparathyroidism

frequently triggers pseudogout attacks. In addition, pseudogout of the knee can be precipitated by arthroscopy or by intra-articular administration of hyaluronan¹⁰⁵ that could reflect proinflammatory mechanisms triggered through the hyaluronan receptor CD44. Parenteral administration of granulocyte colony-stimulating factor (G-CSF)¹⁰⁶ and of bisphosphonates¹⁰⁷ also can trigger pseudogout, the former likely by ignition of smoldering subclinical intra-articular inflammation, the latter theoretically via pyrophosphatase inhibition because bisphosphonates are nonhydrolyzable analogues of PP_i .

Acute and subacute pseudogout can be associated with fever, chills, elevated erythrocyte sedimentation rate, and systemic leukocytosis, particularly with polyarticular involvement and in the elderly.¹⁰⁸ Leukocyte counts in the synovial fluid are substantially elevated, and intraleukocytic CPPD crystals are most often (but not universally) detectable by compensated polarized light microscopy in pseudogout. The attacks typically last for 7 to 10 days but also can be clustered and last for weeks to months. Occasionally the leukocyte count in pseudogout can exceed 50,000 per mm^3 (pseudoseptic arthritis).

Chronic Degenerative and Inflammatory Arthropathies

Acute pseudogout attacks may be interspersed with chronic arthropathy in CPPD crystal deposition disease, though it has been suggested that acute flares of pseudogout may become less common in those with established chronic degenerative CPPD deposition arthropathy.¹⁰⁹ Chronic degenerative arthropathy in CPPD deposition disease commonly affects certain joints that are typically spared in primary OA (e.g., metacarpophalangeal joints, wrists, elbows, glenohumeral joints). The development of cartilage degenerative changes in CPPD deposition disease in both typical and atypical joints for primary OA suggests one or more systemic abnormalities.

Degenerative cartilage disease associated with sporadic CPPD crystal deposition disease may present as destructive arthropathy of the knees, hips, and/or shoulders, particularly in elderly females (Figures 96-5 and 96-6). The CPPD crystal arthropathy-associated degenerative disease can be less or more destructive than that observed in primary OA. For example, patients with primary OA and CPPD crystals have been reported to require knee replacement surgery more often than with primary OA without crystals.¹¹⁰ In another study, 60% of patients undergoing joint replacement had CPPD or BCP crystals (and commonly both) in their knee synovial fluids, and higher mean radiographic scores correlated with the presence of calcium-containing crystals.¹¹¹ However, prospective analysis of CPPD deposition disease that principally involved the knee has suggested that radiographic worsening of degenerative changes may be slow.¹¹² The disease also may not appear to be clinically progressive in the involved knee after substantial periods of follow-up in a subset of patients, though clinical involvement may spread to other joints in the same time frame.¹¹² Most patients develop changes in radiographic extent of chondrocalcinosis over time. But there is no clear correlation between the extent of calcification and progression of CPPD deposition arthropathy. There may be a relatively

Figure 96-5 Radiographic features of calcium pyrophosphate dihydrate arthropathy. **A**, Destructive shoulder arthropathy. **B**, Metacarpophalangeal joint arthropathy. **C**, Knee degenerative joint disease with large subchondral bone cyst. **D**, Wraparound patella (same patient shown in **A**).

Figure 96-6 Chondrocalcinosis of the most commonly affected joints in calcium pyrophosphate dihydrate deposition disease. **A**, Linear calcifications observed in knee menisci and fibrocartilage. **B**, Lateral view showing calcification of the articular cartilage as a line parallel to the femoral condyles. **C**, Calcification of intercarpal joints and triangular ligament. **D**, Calcification of the symphysis pubis fibrocartilage associated with subchondral bone erosions and subchondral increased bone density.

good prognosis for initial presentation of CPPD deposition disease in the knee as acute pseudogout attacks alone.¹¹²

Pseudorheumatoid involvement in a small subset of patients with CPPD deposition disease presents as a chronic, bilateral, symmetric deforming inflammatory polyarthropathy (see Figure 96-4). Many of these patients have bilateral wrist and metacarpophalangeal joint involvement. Wrist tenosynovitis and carpal tunnel syndrome, cubital tunnel syndrome, and tendon rupture may develop. Ingestion of CPPD crystals by synovial lining cells and lysosomal catabolism of such ingested crystals stimulates synovial proliferation, in part via solubilization of the crystalline calcium. Such effects may contribute to regional synovial and periarticular tenosynovial proliferation promoted by CPPD crystal deposition.⁸⁴

Other Clinical Forms of Calcium Pyrophosphate Dihydrate Crystal Deposition

Concentrated (tumoral or pseudotophaceous) CPPD crystal deposition can occur in periarticular structures including tendons, ligaments, bursae, and occasionally in bone.^{104,113} CPPD deposits in tendons (e.g., Achilles, triceps, and obturator tendons) are usually fine and linear on radiographs. Pseudotophaceous deposits of CPPD crystals have been detected in the temporal bone, around the knee and hip, and in the acromioclavicular, temporomandibular, elbow, and small hand joints.¹¹³ Peripheral tumoral CPPD crystal deposits may sometimes present with acute arthritic attacks. Rarely, tumoral CPPD deposits around the knee can mimic osteonecrosis.¹¹⁴ Tumoral CPPD crystal deposition is typically associated with tissue chondroid metaplasia and behaves like a benign but locally aggressive chondroid tumor, with some of the connective tissue invasion and destruction likely mediated by CPPD crystal-induced cell activation.

Axial skeletal CPPD crystal deposition occasionally involves the intervertebral disks, sacroiliac joints, and lumbar facet joints, and radiographic findings such as linear calcification and spinal ankylosis may appear.¹¹⁵ Meningismus and clinical manifestations resembling herniated intervertebral disk, ankylosing spondylitis, and acute pseudogout of lumbar facet joints have been observed.^{115,116} In addition, CPPD deposits within the ligamentum flavum or the transverse ligament of atlas can be sizeable and can progress to cause cervical canal stenosis, cervical myelopathy, and foramen magnum syndrome.¹¹⁷⁻¹¹⁹ Odontoid fracture due to the calcification of the atlantoaxial joint may occur in CPPD deposition disease.¹¹⁷⁻¹²⁰ Thus CPPD deposition disease can factor in the differential diagnosis of patients with neurologic disturbances and painful cervical mass, especially in the elderly.

Familial Chondrocalcinosis

Familial CPPD deposition disease has been described in numerous countries and ethnic groups including kindreds from Czechoslovakia, Holland, France, England, Germany, Sweden, Israel, the United States, Canada, and Japan and may be most prevalent in Chile and Spain. In one English kindred with CPPD disease linked to ANKH mutation on chromosome 5p, recurrent childhood seizures were strongly

associated with later development of CPPD deposition disease.¹²¹ For linkages to ANKH on chromosome 5p, some families manifest early-onset polyarthritis, which can include ankylosing intervertebral and sacroiliac joint disease. In others a late-onset chondrocalcinosis occurs, and the disease can be oligoarticular, mild in intensity and destructiveness, and nearly indistinguishable from idiopathic CPPD deposition disease.^{12,38,48} Kindreds from Argentina and the Alsace region of France linked to 5p did share similar phenotypic features of chondrocalcinosis including early age at onset (third decade of life), common but not universal premature OA, some cases of pseudorheumatoid arthritic peripheral joint disease, and radiographic evidence of fibrocartilage and hyaline cartilage calcifications typical of CPPD deposition.¹²² The most commonly affected joints in these kindreds were the knees and wrists, with involvement of the pubic symphysis and intervertebral disks also described.¹²²

CLINICAL FEATURES OF ARTICULAR BASIC CALCIUM PHOSPHATE CRYSTAL DISEASE

KEY POINTS

Unlike urate and CPPD crystal deposition, acute synovitis due to HA crystal deposition is unusual. Acute inflammatory syndromes including subacromial bursitis and a form of pseudopodagra described in young women may occur in association with periarticular HA crystal deposition in bursae, tendons, ligaments, and soft tissues.

Patients with advanced chronic renal failure, particularly on dialysis, may develop symptomatic articular and periarticular BCP crystal deposition, which may be destructive and involve the axial skeleton. They may resemble or be associated with CPPD deposition disease.

Clinical Features of Pathologic Basic Calcium Phosphate Crystal Deposition in Joint Tissues

Unlike the case for urate and CPPD crystal deposition, acute synovitis due to HA crystal deposition is unusual. But acute inflammatory syndromes including subacromial bursitis and a form of pseudopodagra described in young women¹²³ may occur in association with periarticular HA crystal deposition in bursae, tendons, ligaments, and soft tissues. Patients with advanced chronic renal failure, particularly on dialysis, may develop symptomatic articular and periarticular BCP crystal deposition (Figure 96-7), which may be destructive and involve the axial skeleton.¹²⁴ In some cases of dialysis-dependent renal failure, destructive arthropathy associated with BCP crystal deposition may resemble or be associated with CPPD deposition disease, and monosodium urate crystal deposits in the joint also may occur in the setting. Hyperparathyroidism can promote BCP-associated arthropathy¹²⁵ and periarticular disease including calcific bursitis (see Figure 96-7). Clinically significant periarticular HA crystal deposition also may occur in certain post-traumatic conditions and the systemic autoimmune diseases scleroderma and dermatomyositis.

BCP crystal deposition has a particular predilection for the shoulder (see Chapter 46), where it may manifest as

Figure 96-7 Hydroxyapatite crystal-associated calcific bursitis of the shoulder in a patient with chronic renal failure and secondary hyperparathyroidism. **A**, Chronic soft tissue swelling involving the right shoulder due to calcific right shoulder subacromial bursitis in a middle-aged male with a history of chronic renal failure on hemodialysis. Note the convex contour of the right shoulder compared with the left. **B**, Radiograph showing extensive calcification both within the rotator cuff and the expanded subacromial bursa surrounding the right shoulder joint. Incidental note is made of the resorption of the distal end of the clavicle consistent with the secondary hyperparathyroidism in this patient. **C**, Subacromial bursa fluid from the right shoulder. Note the milk-white appearance with a chalky sediment of the particulate material in the fluid after centrifugation consistent with crystal deposition disease. **D**, Microscopic appearance of bursa fluid aggregates of basic calcium phosphate crystals in the absence of special stains. The particles are irregular but have approximately spherical profiles. (Unstained. Magnification $\times 250$.) **E**, Appearance of the bursa fluid under polarized light microscopy. Importantly, the aggregated particles of basic calcium phosphate crystals demonstrate edge birefringence but do not display intrusive birefringence, as seen in the figure. (Unstained. Magnification $\times 250$.) **F**, Electron photomicrograph of a mononuclear phagocyte from this bursa fluid that contained phagocytosed electron dense (dark black) spherical aggregates of crystals of the basic calcium phosphate hydroxyapatite in three phagolysosomes oriented vertically to the right of the nucleus. Hundreds of tiny needle-shaped hydroxyapatite crystals are clumped in each of these dense aggregates. For perspective, the size of the mononuclear phagocyte is approximately 20 microns, and an individual (nonaggregated) hydroxyapatite crystal is approximately $0.04 \times 0.01 \times 0.01$ microns in size. (Transmission electron microscopy. Magnification $\times 1000$.) **G**, Electron diffraction pattern of hydroxyapatite crystal aggregates. The diffraction rings are indicative of a powder pattern (i.e., small crystals). The position of the bright rings with d-spacings = 3.44 and 2.81 Å are characteristic of hydroxyapatite (calcium apatite). (Courtesy Dr. Ken Pritzker, Mount Sinai Hospital Pathology Department, University of Toronto, Ontario, Canada.)

calcific tendinitis of the rotator cuff or as a destructive process associated with rotator cuff tear, which is most prevalent in the elderly and more common in females.¹²⁶ Abundant intra-articular BCP crystalline material is typically present in the distinctive noninflammatory syndrome of rotator cuff tear and marked cartilage degeneration, an entity termed MSS, *cuff tear arthropathy*, or *apatite-associated destructive arthritis*.¹²⁶ Mechanical instability of the shoulder due to rotator cuff tear may be the driving force in many of these patients, with consequent release of BCP crystals from

bone fragments into the joint space promoting secondary synovitis and connective tissue destruction. The process may be bilateral but is generally worse on the side of the dominant hand. Substantial glenohumeral joint effusions are typically seen, and synovial fluid is often blood stained but contains, at most, relatively low numbers of mononuclear leukocytes. Joints other than the shoulder such as the knee and hip can be affected by a condition similar to MSS, sometimes in the same individual with shoulder involvement. In contrast to primary OA, lateral tibiofemoral

compartment involvement is common in BCP-associated destructive knee arthropathy. Concurrent CPPD deposition, biomechanical abnormalities, chronic renal failure, and neuropathic factors appear to be predisposing factors. A kindred with familial OA and apparent Milwaukee shoulder-knee syndrome (MSKS) had an unusual type of degenerative joint disease with both intra-articular and periarticular calcifications.¹²⁷

Aging itself is a factor in articular cartilage BCP crystal deposition.¹²⁸ Multiple studies of synovial fluids and cartilage specimens from OA including recent work that has taken advantage of high-resolution means for BCP crystal detection¹²⁹ have suggested that deposition of intra-articular BCP crystalline material including HA in the pericellular matrix of chondrocytes and the capacity of joint cartilages to form such deposits are intimately linked with OA, as well as increased chondrocyte hypertrophy and severity of OA.^{111,130-132} One limitation of some of these studies is that cartilages were fixed before analysis, and calcifications can develop as a fixation artifact. However, unequivocally, cartilage and synovial fluid BCP crystals, frequently in conjunction with CPPD crystals, are commonly detectable in advanced disease of the knee at the time of total joint replacement for OA.^{111,132} Traffic of crystals from articular cartilage to synovium can promote calcific synovial crystal deposits at or just beneath the synovial surface, and synovium-derived rice bodies can give rise to BCP crystal deposits released into the joint space.^{133,134}

Collectively, the abundance of HA and CPPD crystals in OA joints is likely significant under many clinical circumstances because HA and CPPD crystal-induced synovial proliferation, cytotoxic effects on chondrocytes, and synovial and chondrocyte MMP expression have the potential to promote OA progression.^{132,133} Better surveys of joint tissues with advanced methods for detection of BCP crystals,^{132,135,136} in particular, will be necessary to improve understanding of the clinical impact of these calcific crystals on OA.

DIAGNOSIS AND DIAGNOSTIC TESTS

KEY POINTS

Presence of radiographic evidence for chondrocalcinosis is a common finding in the aged and does not necessarily indicate that the patient's symptomatic articular problem is due to CPPD deposition disease, which is often asymptomatic.

The use of compensated polarized light microscopy is essential to confirm the presence of positively birefringent CPPD crystals, though it should be noted that some CPPD crystals are nonbirefringent.

Patients with arthritis in whom CPPD deposition disease is part of the differential diagnosis can be screened by plain radiographs, but high-resolution ultrasound of the affected joint is a useful and sensitive alternative approach.

Differential Diagnosis

CPPD deposition disease can imitate a number of other conditions and vice versa (see Table 96-3), which mandates

attention to fulfillment of diagnostic criteria for CPPD deposition disease (see Table 96-1) and necessitates careful adherence to a diagnostic algorithm (Figure 96-8). Conversely, it is important to note that presence of radiographic evidence for chondrocalcinosis is a common finding in the aged and does not necessarily indicate that the patient's symptomatic articular problem is due to CPPD deposition disease, which is often asymptomatic. The demonstrable presence of CPPD crystals in synovial fluid or in tissues using compensated polarized light microscopy (as discussed earlier for gout vs. pseudogout) is definite evidence for CPPD deposition disease. Though weakly birefringent relative to urate crystals and often rhomboid in shape, CPPD crystals can be rod shaped and intracellular, thereby resembling urate crystals. Thus the use of compensated polarized light microscopy is essential to confirm the presence of positively birefringent CPPD crystals, though it should be noted that some CPPD crystals are nonbirefringent.¹³⁷ The appearance and number of CPPD crystals can change with storage. Therefore clinicians should examine relatively fresh specimens collected in vials free of calcium-chelating anticoagulants such as EDTA. Cytocentrifugation increases sensitivity of detection of rare CPPD crystals, as observed in one study that highlighted approximately 75% to 78% of synovial fluid samples (of subjects with gout and OA) having both urate and CPPD crystals.¹³⁸

The ability of pseudogout to mimic septic arthritis (pseudoseptic arthritis) and vice versa underscores the diagnostic importance of arthrocentesis with appropriate synovial fluid crystal analysis and, in many instances, concomitant exclusion of joint infection. Significantly, crystal deposits can be “enzymatically strip-mined” by inflammation associated with joint sepsis. Hence CPPD (as well as other crystals) may be observed free in the joint fluid and within synovial fluid leukocytes in an infected joint.

Diagnosis of CPPD deposition disease before age 55, particularly if CPPD deposition is widespread, should prompt differential diagnostic consideration of a primary metabolic or familial disorder (see Table 96-2). In the elderly, presentation of CPPD deposition as diffuse pain and fever of unknown origin⁶⁶ can mimic infection, polymyalgia rheumatica, and RA. A false-positive rheumatoid factor (RF) test is common in the elderly ($\geq 30\%$ positivity). Thus patients with pseudorheumatoid CPPD deposition disease are often RF seropositive.

Differential Diagnostic Considerations for Basic Calcium Phosphate Crystal Deposition

BCP crystals may be detected as nonbirefringent globular clumps within leukocytes in some synovial and bursal fluids (see Figure 96-7), and BCP crystal clumps stain with the calcium-binding dye Alizarin red S under light microscopy.^{139,140} CPPD crystals can also be detected using Alizarin red S but stain more weakly than BCP crystals. Relative paucity of osteophytes (so-called *atrophic degenerative arthritis*) on plain radiographs and the sizeable glenohumeral joint effusions with abundant synovial fluid BCP crystalline material associated with MSS help distinguish MSS from primary OA of the glenohumeral joint. However, destructive, neuropathic shoulder arthropathy due to syringomyelia or alcoholism sometimes merits consideration in the

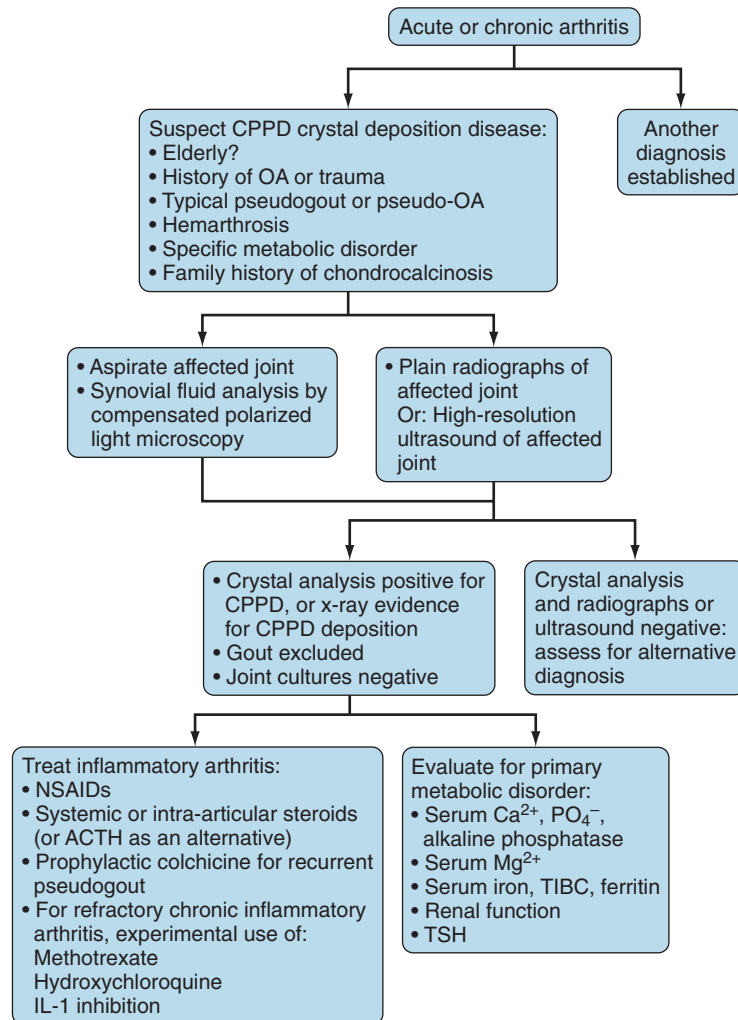

Figure 96-8 Algorithm for diagnosis, evaluation, and treatment of calcium pyrophosphate dihydrate (CPPD) deposition disease. The algorithm is discussed in detail in the text. Treatment options are in line with those recently advanced by the European League Against Rheumatism. ACTH, adrenocorticotrophic hormone; IL-1, interleukin-1; NSAIDs, nonsteroidal anti-inflammatory drugs; OA, osteoarthritis; TIBC, total iron binding capacity; TSH, thyroid-stimulating hormone. (From Guerne P-A, Terkeltaub R: *Calcium pyrophosphate dihydrate crystal deposition: epidemiology, clinical features, diagnosis, and treatment*. In Terkeltaub R, editor: *Gout and other crystal arthropathies*, Philadelphia, 2011, Elsevier.)

differential diagnosis of MSS (see Chapter 47). Oxalate crystal deposition arthropathy can be a major differential diagnostic consideration with BCP-associated arthritis and periarticular calcifications in dialysis-dependent renal failure.

Chronic CPPD Deposition Arthropathy, BCP Crystal-Associated Arthritis, and Use of Plain Radiographs in Diagnosis

Chronic arthritis in CPPD deposition disease has several clinical and plain radiographic features helpful in differentiating it from OA. These include involvement at sites uncommon for primary OA such as the wrist, metacarpophalangeal joints, elbow, or shoulder, as well as radiographic heavy punctate and linear calcifications in fibrocartilages, articular (hyaline) cartilages, and joint capsules, especially if bilaterally symmetric (see Figures 96-5 and 96-6). It should be noted that faint or atypical calcifications may be due to BCP-related vascular calcifications. Deposition of nonpathologic dicalcium phosphate dihydrate (DCPD)

($\text{CaHPO}_4 \cdot 2\text{H}_2\text{O}$, calcium-to-phosphate ratio, 1) (“brushite”) crystals has been thought to cause some atypical calcifications, but brushite crystals can arise as an artifact of acid preparation of calcified tissue for pathologic analyses.¹⁴¹

CPPD crystal deposits often appear as broad linear streaks or linear “chunks” in articular hyaline and fibrocartilages on plain radiographs, whereas BCP crystal deposits in articular cartilage require high-resolution radiography for detection. Only a pattern of “atrophic” degenerative arthritis without osteophytes and variable subchondral bone thickening may be seen on plain radiographs of BCP arthritis in the shoulder and other large joints.

Patients with arthritis in whom CPPD deposition disease is part of the differential diagnosis can be screened radiologically by obtaining an anteroposterior (AP) view of each knee, an AP view of the pelvis (to detect symphysis pubis involvement, which is quite common), and posteroanterior (PA) views of both hands that include visualization of both wrists (see Figures 96-5 and 96-6). Calcific deposits may or may not be detectable by x-ray screening of these areas in

CPPD deposition disease. In this circumstance, radiographic evidence other than chondrocalcinosis may point to the correct diagnosis.¹⁴² For example, radiographic findings suggestive of CPPD deposition disease, as opposed to primary OA, include radiocarpal or marked patellofemoral joint space narrowing, especially if isolated (such as the patella “wrapped around” the femur), as well as scaphoid-lunate widening and femoral cortical erosion superior to the patella. Severe progressive degeneration in the knee with subchondral bony collapse (microfractures) and fragmentation with formation of intra-articular radiodense bodies is a feature of CPPD presenting as a “pseudoneuropathic” joint. CPPD deposition disease involving the metacarpophalangeal joints can be distinguished radiographically from RA by metacarpal squaring associated with “beaklike” osteophytes and subchondral cyst formation. Tendon calcifications (e.g., Achilles, triceps, and obturator tendons) are a valuable differential diagnostic feature of CPPD deposition. Osteophyte formation is more variable with CPPD deposition disease than with OA. Clearly, x-ray findings may not correlate with pathologic and clinical manifestations in CPPD disease. For example, the correlation between radiographic and pathologic findings was only 39.2% in a study of patients via knee arthroscopy.¹⁴³

High-Resolution Ultrasound and Advanced Imaging for Diagnosis of CPPD and BCP Crystal Deposition Diseases

Ultrasound can clearly detect aggregated BCP-related calcifications outside of joint cartilages including in the rotator cuff of the shoulder. In addition, in small, preliminary studies, high-resolution ultrasound (e.g., in the 6 to 13 MHz range using the current generation of equipment) detection of CPPD crystal deposits in joints has correlated well with positive results for synovial fluid analysis and has detected CPPD in some patients in whom plain radiographs were negative in the affected joint.¹⁴⁴⁻¹⁴⁹ Preliminary criteria proposed for CPPD calcifications by ultrasound are summarized in Table 96-4, and Figure 96-9 (and Supplemental Figure

Table 96-4 Preliminary Criteria for Calcium Pyrophosphate Dihydrate (CPPD) Crystal Deposition Diagnosis by High-Resolution Ultrasound

1. All CPPD deposits are hyperechoic and present as one of the following patterns:
Thin hyperechoic bands, parallel to the surface of the hyaline cartilage (frequently observed in the knee)
A “punctate” pattern, composed of several thin hyperechoic spots, more common in fibrous cartilage and in tendons
Homogeneous hyperechoic nodular or oval deposits localized in bursae and articular recesses (frequently mobile)
2. CPPD crystal deposit calcifications always have a sparkling appearance and create posterior shadowing only when they reach dimensions of greater than 10 mm. In contrast, calcifications that present a hypoechoic appearance with posterior shadowing even at an early stage (2-3 mm in diameter) are considered as crystalline deposits of another nature, most commonly due to basic calcium phosphate crystal deposition disease.

Modified from Frediani B, Filippou G, Falsetti P, et al: Diagnosis of calcium pyrophosphate dihydrate crystal deposition disease: ultrasonographic criteria proposed, *Ann Rheum Dis* 64:638–640, 2005.

96-3 on www.expertconsult.com) illustrates characteristic ultrasound features of CPPD deposits. Further validation is necessary for reliance on ultrasound without radiography in CPPD diagnosis.

The ultrasound approach is likely most specific for detection of CPPD crystal deposition in fibrocartilages (e.g., triangular fibrocartilage of the wrist and the midzones of articular hyaline cartilages (see Figure 96-9). Ultrasound, without use of synovial fluid analysis in diagnosis of acute pseudogout, runs the risk of missing other conditions such as infectious arthritis. Gout can generally be differentiated, particularly because redundant hyperechoic contouring of the cartilage surface is seen more in gout, whereas CPPD crystal deposition disease is typically visualized within the cartilage.¹⁴⁵ Because enthesopathies other than CPPD disease can also give rise to calcification of tendons and plantar fascia, the diagnostic value for CPPD disease of ultrasound detection of calcification in plantar fascia and Achilles tendon¹⁵⁰ is not yet clear.

Limitations of ultrasound include difficulty in visualizing crystal deposits in deep recesses of the joint space, the need for a high-resolution machine of the current generation, dependence on the skill of the ultrasonographer, and aforementioned issues with specificity of findings.

Dual-energy computed tomography has not been specifically studied for CPPD detection but is useful for specific discrimination of urate from BCP deposits.¹⁵¹ Magnetic resonance imaging (MRI) is not yet a reliable approach for detecting CPPD crystal deposition disease due to a lack of mobile protons in CPPD crystals, and nonenhanced MRI is less sensitive in detecting knee meniscal fibrocartilage calcification than hyaline cartilage calcification.¹⁵²

Laboratory Diagnostic Tests for CPPD and BCP Crystal Deposition Disease

Conventional radiography or ultrasound is usually the first method to evaluate patients with suspected chondrocalcinosis, but thorough laboratory evaluation of the newly diagnosed CPPD disease patient routinely includes serum levels of calcium, phosphorus, magnesium, alkaline phosphatase, ferritin, iron and total iron-binding capacity, and thyroid-stimulating hormone (TSH) (see Figure 96-8).

Specialized techniques beyond Alizarin red S staining such as x-ray diffraction, Raman spectroscopy, Fourier transform infrared spectroscopy, atomic force microscopy, or transmission electron microscopy showing electron-dense clumps of needle-like crystals may be necessary to confirm BCP crystal deposition (see Figure 96-7).¹²⁹

Cycentrifugation can increase sensitivity of CPPD detection in synovial fluid.¹³⁸ Under conditions where synovial fluid specimens are not fresh (or stored at 4° C for analysis after significant delay¹⁵³), Gram stain and Diff Quik staining methods for crystal analysis in synovial fluids have been suggested to provide information beyond that from compensated polarized light microscopy.^{154,155} Demonstration of CPPD crystals in articular tissues (see Figure 96-3) can be difficult in specimens stained with hematoxylin and eosin because the acidity of hematoxylin solutions promotes decalcification. However, the decalcifying effect of hematoxylin can be diminished by limiting the staining period with Mayer’s hematoxylin to 3 minutes.¹⁵⁶

TREATMENT

KEY POINTS

CPPD deposition disease treatment involves alleviation and prophylaxis of acute arthritic attacks, but therapy to lessen chronic and anatomically progressive sequelae of crystal deposition is not well developed for CPPD disease.

The approach to pseudogout treatment is similar to that for acute gout.

Calcium Pyrophosphate Dihydrate Deposition Disease

A treatment algorithm is presented at the bottom of Figure 96-8 that is consonant with the preliminary EULAR guidelines.^{156a} As in gout (see Chapter 95), therapeutic approaches to patients with CPPD deposition disease involve treatment and prophylaxis of acute arthritic attacks, but therapy to lessen chronic and anatomically progressive sequelae of crystal deposition is not well developed for CPPD (Table 96-5). Reduced meniscal calcification was reported over a 10-year period in association with administration of oral magnesium to a patient with secondary CPPD deposition disease caused by hypomagnesemia.¹⁵⁷ However, there is no specific treatment validated to prevent or lessen crystal deposition of idiopathic CPPD deposition disease. Metabolic disorders that secondarily cause CPPD crystal deposition obviously require treatment. However, the potential benefits for prevention of chondrocalcinotic cartilage degeneration in the appropriate treatment of

Table 96-5 Therapeutics for Calcium Pyrophosphate Dihydrate (CPPD) Crystal Deposition Disease

Proven Benefits
NSAIDs or COX-2 inhibitors
Intra-articular corticosteroids
Systemic corticosteroids
ACTH
Prophylactic low-dose colchicine
Possible Benefits Already Observed Clinically
Methotrexate for refractory chronic inflammation and recurrent pseudogout
Oral magnesium (for patients with hypomagnesemia)
Theoretic Benefits
Phosphocitrate
Caspase-1 or IL-1 antagonism for CPPD crystal-induced inflammation
Hydroxychloroquine for refractory chronic inflammation
TLR2 antagonism for CPPD-associated degenerative arthropathy
Oral calcium supplementation to suppress PTH levels
ANKH anion channel blockade (probenecid)
NPP1 inhibition
TG2 inhibition
Polyphosphates
Promotion of crystal dissolution by alkaline phosphatase or polyamines

ACTH, adrenocorticotrophic hormone; COX-2, cyclooxygenase-2; IL-1, interleukin-1; NPP1, nucleotide pyrophosphate phosphodiesterase 1; NSAIDs, nonsteroidal anti-inflammatory drugs; PTH, parathyroid hormone; TG2, transglutaminase 2; TLR2, Toll-like receptor 2.

hemochromatosis and hyperparathyroidism are unclear because the ability to detect chondrocalcinosis radiologically is usually indicative of advanced crystal deposition disease.

Episodes of pseudogout generally respond to nonsteroidal anti-inflammatory drugs (NSAIDs) (including cyclooxygenase-2 inhibitors) and/or intra-articular steroids, though sometimes more slowly than in gout. Systemic glucocorticosteroids or adrenocorticotrophic hormone (ACTH),^{158,159} generally given as described for acute gout (see Chapter 95), appear effective in most cases of acute pseudogout. The response to colchicine bolus is less consistent than that usually seen in acute gout. Intravenous colchicine is not recommended as treatment for pseudogout and was withdrawn from active marketing in 2008 by the U.S. Food and Drug Administration. However, pseudogout episodes can be diminished in frequency by low-dose daily colchicine prophylaxis, as for gouty arthritis. The self-limited nature of most acute pseudogout attacks in the knee can sometimes be accelerated by simple arthrocentesis and thorough drainage of the joint effusion, but there are currently no data for measures such as tidal irrigation in CPPD deposition disease, unlike the case for MSS.^{160,161}

Hydroxychloroquine¹⁶² has been suggested to be of some benefit to patients with refractory chronic polyarticular CPPD deposition disease and to reduce flares of pseudogout, and it has theoretic benefits by potentially stabilizing phagolysosomes to suppress NLRP3 inflammasome activation in response to CPPD crystal uptake. Methotrexate was promising to patients with refractory chronic polyarticular CPPD deposition disease and to reduce flares of pseudogout, though in an exploratory study limited to five consecutive patients, and with patients prior to methotrexate as their own controls.¹⁶³ IL-1 antagonism (e.g., with off-label use of anakinra) has had anecdotal success,^{164,165} whereas breakthrough pseudogout has been reported during TNF antagonist therapy.¹⁶⁶ Collectively, at this time, there is insufficient evidence basis for hydroxychloroquine, methotrexate, and IL-1 antagonism as standard therapies for refractory inflammation in CPPD crystal deposition disease.

Effective cartilage-preserving therapy is still lacking in idiopathic chronic progressive CPPD deposition disease. Only limited evidence suggests that OA patients with cartilage calcification respond distinctly to arthroscopic irrigation and daily low-dose colchicines,¹⁶⁷⁻¹⁶⁹ but further substantiation is necessary. There is currently no evidence to support arthroscopic débridement as a treatment modality for CPPD deposition disease. There is insufficient evidence for beneficial effects of intra-articular hyaluronan therapy in CPPD deposition disease of the knee, and risks of precipitating pseudogout appear significant with this treatment modality, as cited earlier.

Basic Calcium Phosphate Crystal Arthropathies

NSAIDs and local glucocorticoid injection (Table 96-6) are effective treatment options for BCP crystal-associated calcific tendinitis and subacromial bursitis (see Chapter 46). BCP crystal-associated inflammation of the rotator cuff and subacromial bursa of the shoulder can be successfully treated using needle aspiration, irrigation, and steroid injections. Ultrasound-guided techniques, which promote resorption of

Table 96-6 Therapeutics for Articular and Periarticular Basic Calcium Phosphate (BCP) Crystal Deposition

Proven Benefits
NSAIDs or selective COX-2 inhibitors
Local corticosteroid injection
Local irrigation
High-frequency therapeutic ultrasound to degrade BCP crystal deposits
Theoretic Benefits
Phosphocitrate
Modulators of ANKH (e.g., probenecid), ENPP1, or transglutaminase 2

COX-2, cyclooxygenase-2; ENPP1, ectonucleotide pyrophosphatase/phosphodiesterase 1; NSAIDs, nonsteroidal anti-inflammatory drugs.

rotator cuff and bursal calcifications, can enhance the success of such approaches.^{170,171} Tidal irrigation may be of benefit for symptoms and function in MSS.^{152,160}

Future Directions in Treatment

A potential factor that helps suppress the prevalence of chondrocalcinosis in China is high oral calcium intake, which can limit PTH production by the parathyroid. Specifically, calcium levels in tap water in Beijing were 12- to 20-fold higher than that in Framingham, whereas no difference was found in levels of magnesium in the aforementioned study of China versus USA chondrocalcinosis prevalence by Zhang and colleagues.⁹ Deficient calcium intake in aging is a major public health problem in Western countries. It is possible that chondrocalcinosis is more of an environmentally mediated finding than previously recognized, via subclinical variability in calcium intake and parathyroid function. Given the current lack of effective, rational therapies to prevent or lessen idiopathic CPPD crystal deposition, further study of the potential prophylactic and therapeutic benefits of dietary calcium supplementation on chondrocalcinosis is warranted.

The potential to develop therapies for both CPPD and BCP crystal-associated arthropathies based on new molecular targets has been elevated by identification of ANKH, ENPP1, and TG2 as specific molecular mediators of cartilage calcification. Intriguingly, the anion transport inhibitor probenecid suppresses ANKH-induced and TGF- β -induced increases in extracellular PP_i in vitro.^{36,38,172} Prevention of CPPD deposition by polyphosphates or promotion of CPPD dissolution by depot alkaline phosphatase and by pyrophosphatase activation-promoting polyamines could provide alternative therapeutic approaches.¹⁷³⁻¹⁷⁵ However, incomplete CPPD crystal dissolution by intra-articular lavage of patients with chondrocalcinosis of the knees with disodium EDTA and magnesium ions in the past was a therapeutic failure in that insignificant amounts of CPPD were removed and all subjects developed postlavage attacks of pseudogout mediated by crystal shedding.¹⁷⁶

The PP_i analogue phosphocitrate, a natural compound in mammalian mitochondria and in the urinary tract, is a potent inhibitor of HA crystal formation.¹⁷⁷ Phosphocitrate inhibits nitric oxide-induced calcification of cartilage and also inhibits both HA and CPPD crystal-associated cell

stimulation including induction of MMP-3 in fibroblasts.¹⁷⁸ Systemic phosphocitrate treatment suppresses ankylosing ossification in murine progressive ankylosis of *ank/ank* mice.¹⁷⁹ Moreover, an analogue of phosphocitrate (CaNaPC) decreased both the abundant meniscal cartilage HA deposition and the continuous progression of OA in the Hartley guinea pig model of spontaneous knee OA.¹⁸⁰ The CaNaPC treatment did not exert therapeutic effects in a rabbit knee hemimeniscectomy model of OA in which there was an absence of intra-articular calcification.¹⁸⁰ Such results suggest that phosphocitrate acts on calcification-mediated mechanisms of dysregulation of joint biomechanics and cartilage degeneration without exerting nonspecific chondroprotective effects. Further clinical development of phosphocitrate would be of interest but has been slowed in part by low bioavailability unless given parenterally.¹⁷⁷

The use of bisphosphonates as PP_i analogues can be beneficial in some cases of soft tissue calcification with HA. Lastly, the identified roles of TLR2 in chondrocyte responsiveness to CPPD crystals,⁹² of TLR4 in hydroxyapatite crystal-induced inflammatory responses,¹⁸¹ and of NLRP3 inflammasome-mediated caspase-1 activation and IL-1 β processing in CPPD crystal-induced inflammation⁹³ suggest certain mediators of innate immunity including TLR2, TLR4, caspase-1, and IL-1 β to be potential therapeutic targets for human forms of CPPD and hydroxyapatite crystal-driven inflammation and connective tissue destruction.

OUTCOME

KEY POINTS

It is not clear whether the presence of CPPD crystals in primary knee OA is a predictive factor for more frequent knee replacement surgery, despite the fact that CPPD crystals are frequently found in OA knee tissues at the time of total joint arthroplasty.

There is no clear correlation between the extent of calcification and progression of primary CPPD deposition arthropathy.

The presence of CPPD crystals in primary knee OA had been proposed to be a predictive factor for more frequent knee replacement surgery.¹¹⁰ Moreover, mean radiographic scores directly correlated with the presence of calcium-containing crystals in OA in patients at the time of total joint arthroplasty.¹¹¹ However, degenerative cartilage disease associated with sporadic CPPD crystal deposition disease may be less destructive than that observed in primary OA. For example, prospective analysis of CPPD deposition disease of the knee suggested that radiographic worsening of degenerative arthritis was slow to progress.⁶⁷ Typically, changes in radiographic extent of chondrocalcinosis are observed over time,⁶⁷ but there is no clear correlation between the extent of calcification and progression of CPPD deposition arthropathy.

In the Boston OA Knee Study (BOKS) and in the Health, Aging and Body Composition (Health ABC) Study¹⁸² the relationship between chondrocalcinosis and the progression of knee OA was prospectively evaluated

longitudinally using MRI. In BOKS, knees with chondrocalcinosis had a decreased risk of cartilage loss compared with knees without chondrocalcinosis and there was no difference in risk in Health ABC. Stratification by the presence of intact or damaged knee menisci produced comparable results within each cohort. In a Thai study, CPPD crystal deposition disease was identified radiographically and/or by synovial fluid analysis in 52.9% of 102 patients undergoing total knee arthroplasty.¹⁸³ Patients with and without chondrocalcinosis did not differ in difficulties in performing daily activities or treatment, and those with chondrocalcinosis did not undergo knee arthroplasty at an earlier age than those without chondrocalcinosis.

In the setting of OA, the processes leading to matrix calcification had been regarded to reflect passive secondary consequences of advanced cartilage pathology. Moreover, joint inflammation induced by deposited crystals was thought to be the primary determinant of the clinical impact of chondrocalcinosis on the progression of OA. The aforementioned studies and advances in understanding the pathogenesis of OA and chondrocalcinosis paint a different picture of the impact of chondrocalcinosis in OA. In essence, the dysregulated cartilage matrix repair that generates cartilage calcification may be as effective (or in some cases more effective) at slowing cartilage tissue failure than other phenotypes of cartilage repair in OA.

Familial Autoinflammatory Syndromes

ANNA SIMON • JOS W.M. VAN DER MEER •
JOOST P.H. DRENTH

KEY POINTS

Autoinflammatory disorders are characterized by recurrent or chronic inflammation without signs of infection or autoimmunity.

Dysregulation of the interleukin-1 β (IL-1 β) pathway is central to many autoinflammatory syndromes, especially the cryopyrin-associated periodic syndromes, deficiency of the IL-1 receptor antagonist, and familial Mediterranean fever.

The need for a definite diagnosis in the familial autoinflammatory syndromes has increased because of advances in treatment options.

A severe complication is type amyloid A amyloidosis, which often leads to renal failure; the risk of this complication is greatly reduced when patients receive adequate treatment.

In a substantial portion of patients presenting with a clear autoinflammatory phenotype, the diagnosis can remain elusive, which indicates that other disorders remain to be discovered.

Because of the central role of IL-1 β in many autoinflammatory diseases, a trial of IL-1 β inhibiting therapy can be warranted for diagnostic and therapeutic purposes.

The familial autoinflammatory syndromes, often referred to as *hereditary periodic fever syndromes*, comprise rare hereditary disorders with a common phenotype of lifelong, recurrent inflammatory episodes, characterized by inflammatory symptoms such as fever, abdominal pain, diarrhea, rash, or arthralgia.¹ Between the fever episodes, patients with most of these syndromes generally feel healthy and function normally. Routine laboratory investigations during a fever attack invariably reveal a severe acute-phase response with a high erythrocyte sedimentation rate, leukocytosis, and high concentrations of acute-phase proteins such as C-reactive protein (CRP) and serum amyloid A (SAA). The inflammatory episodes occur without an obvious trigger, although some patients note a relationship to physical stimuli (e.g., exposure to cold), emotional stress, or the menstrual cycle. The episodes resolve spontaneously in days or weeks. Patients go undiagnosed for years, generating a high level of discouragement and frustration for patients and physicians when no diagnosis is made.^{2,3} The term *autoinflammatory*, coined by McDermott and colleagues in 1999,⁴ describes the phenotype of recurrent, acute

inflammatory responses. It is preferable to the term *autoimmune* in these cases because typical autoimmune phenomena are not found; the defect is located more in the innate immune system than the acquired immune system.⁵

Several genetically distinct types of hereditary autoinflammatory syndromes are recognized. Despite the common phenotype described previously, these can often be differentiated clinically by specific characteristics, in particular mode of inheritance, age of onset, average duration of the fever episodes and the fever-free interval, geographic region of origin of the patient, and occurrence of long-term complications such as amyloidosis or deafness (Table 97-1 and Figure 97-1). A significant number of patients with a periodic fever phenotype still do not fit into this genetically based classification, probably representing additional (genetic) defects that can lead to autoinflammatory disease. This chapter describes the seven best characterized familial autoinflammatory syndromes at this time in detail.

DIFFERENTIAL DIAGNOSIS

When a patient has had recurrent fever episodes for more than 2 years, it is increasingly unlikely that these are caused by an infection or a malignant disorder. The differential diagnosis at that time may include numerous inflammatory disorders such as juvenile rheumatoid arthritis, adult-onset Still's disease, inflammatory bowel disease, Schnitzler syndrome, and Behçet's disease, in addition to the hereditary periodic fever syndromes (Table 97-2). Because the hereditary syndromes are rare (except for familial Mediterranean fever [FMF] in individuals with a distinct ethnic background), the more common diagnoses should usually be excluded first.

The mainstay of the diagnosis of hereditary autoinflammatory syndromes is clinical assessment, with a detailed medical and family history, and preferably at least one observation of the patient during a fever episode because physical examination of the patient in a period of remission is seldom abnormal. Another helpful clue, although not pathognomonic, is often gained from knowing the patient's ethnic origin. This clinical assessment often yields enough information to build a differential diagnosis of the specific familial autoinflammatory syndromes (see Table 97-1) to determine the direction of genetic testing (Figure 97-2).

When the specific diagnosis remains elusive, a trial treatment with an interleukin-1 (IL-1) inhibitor (e.g., anakinra) can give a diagnostic clue. A significant proportion of patients that suffer from an autoinflammatory disease "not otherwise specified" respond well to treatment with anakinra; we even use the (temporary) label of "anakinra-responsive disease" for this category in daily practice.

Table 97-1 Differential Diagnosis of Familial Autoinflammatory Syndromes

	Mevalonate Kinase (MKD) Deficiency			Cryopyrin-Associated Periodic Syndrome (CAPS)				
	Familial Mediterranean Fever (FMF)	Hyper-immunoglobulin D Syndrome (HIDS)	Mevalonic Aciduria	Tumor Necrosis Factor Receptor-Associated Periodic Syndrome (TRAPS)	Familial Cold Autoinflammatory Syndrome (FCAS)	Muckle-Wells Syndrome (MWS)	Chronic Infantile Neurologic Cutaneous and Articular Syndrome (CINCA)	Deficiency of IL-1 Receptor Antagonist (DIRA)
Mode of Inheritance	Autosomal recessive	Autosomal recessive	Autosomal recessive	Autosomal dominant	Autosomal dominant	Autosomal dominant	Autosomal dominant	Autosomal recessive
Age at Onset (yr)	<20	<1	<1	<20	<1	<20	<1	Birth, <4 wk
Duration of attack (days)*	<2	4-6	4-5	>14	<2	1-2	?	Continuous
Cutaneous Involvement	Erysipelas-like erythema	Maculopapular rash	Morbiliform rash	Migratory rash, overlying area of myalgia	Cold-induced urticaria-like lesions	Urticaria-like rash	Urticaria-like lesions	Generalized pustulosis
Musculoskeletal Involvement	Monoarthritis common	Arthralgia, occasional oligoarthritis	Arthralgia common	Severe myalgia common; occasional frank monoarthritis	Arthralgia common; occasional mild myalgia	Lancing limb pain, arthralgia common; arthritis can occur	Epiphyseal bone formation	Sterile pustulous osteomyelitis
Abdominal Involvement	Sterile peritonitis common	Splenomegaly, severe pain common	Splenomegaly, pain may occur	Severe pain common	None	May occur	Hepatospleno-megaly	
Eye Involvement	Uncommon	Uncommon	Uncommon	Conjunctivitis and periorbital edema common	Conjunctivitis	Conjunctivitis; sometimes optic nerve elevation	Papilledema with possible loss of vision, uveitis	
Distinguishing Clinical Symptoms	Erysipelas-like erythema	Prominent cervical lymphadenopathy	Dysmorphic features, neurologic symptoms	Migratory nature of myalgia and rash, periorbital edema	Cold-induced urticaria-like lesions	Sensorineural hearing loss	Chronic aseptic meningitis, sensorineural hearing loss, arthropathy	
Gene Involved	MEFV	MVK	MVK	TNFRSF1A	CIAS1 = NLRP3	CIAS1 = NLRP3	CIAS1 = NLRP3	IL-1RN
Protein Involved	Pyrin (marennostrin)	Mevalonate kinase	Mevalonate kinase	Type 1 tumor necrosis factor receptor	Cryopyrin	Cryopyrin	Cryopyrin	IL-1RA

*Duration may vary; this is a typical duration.

Note: For details on Blau syndrome, DIRA, and pyogenic sterile arthritis, pyoderma gangrenosum, and acne (PAPA) syndrome, see text.

Modified from Hull KM, Shoham N, Chae JJ, et al: The expanding spectrum of systemic autoinflammatory disorders and their rheumatic manifestations. *Curr Opin Rheumatol* 15:61-69, 2003.

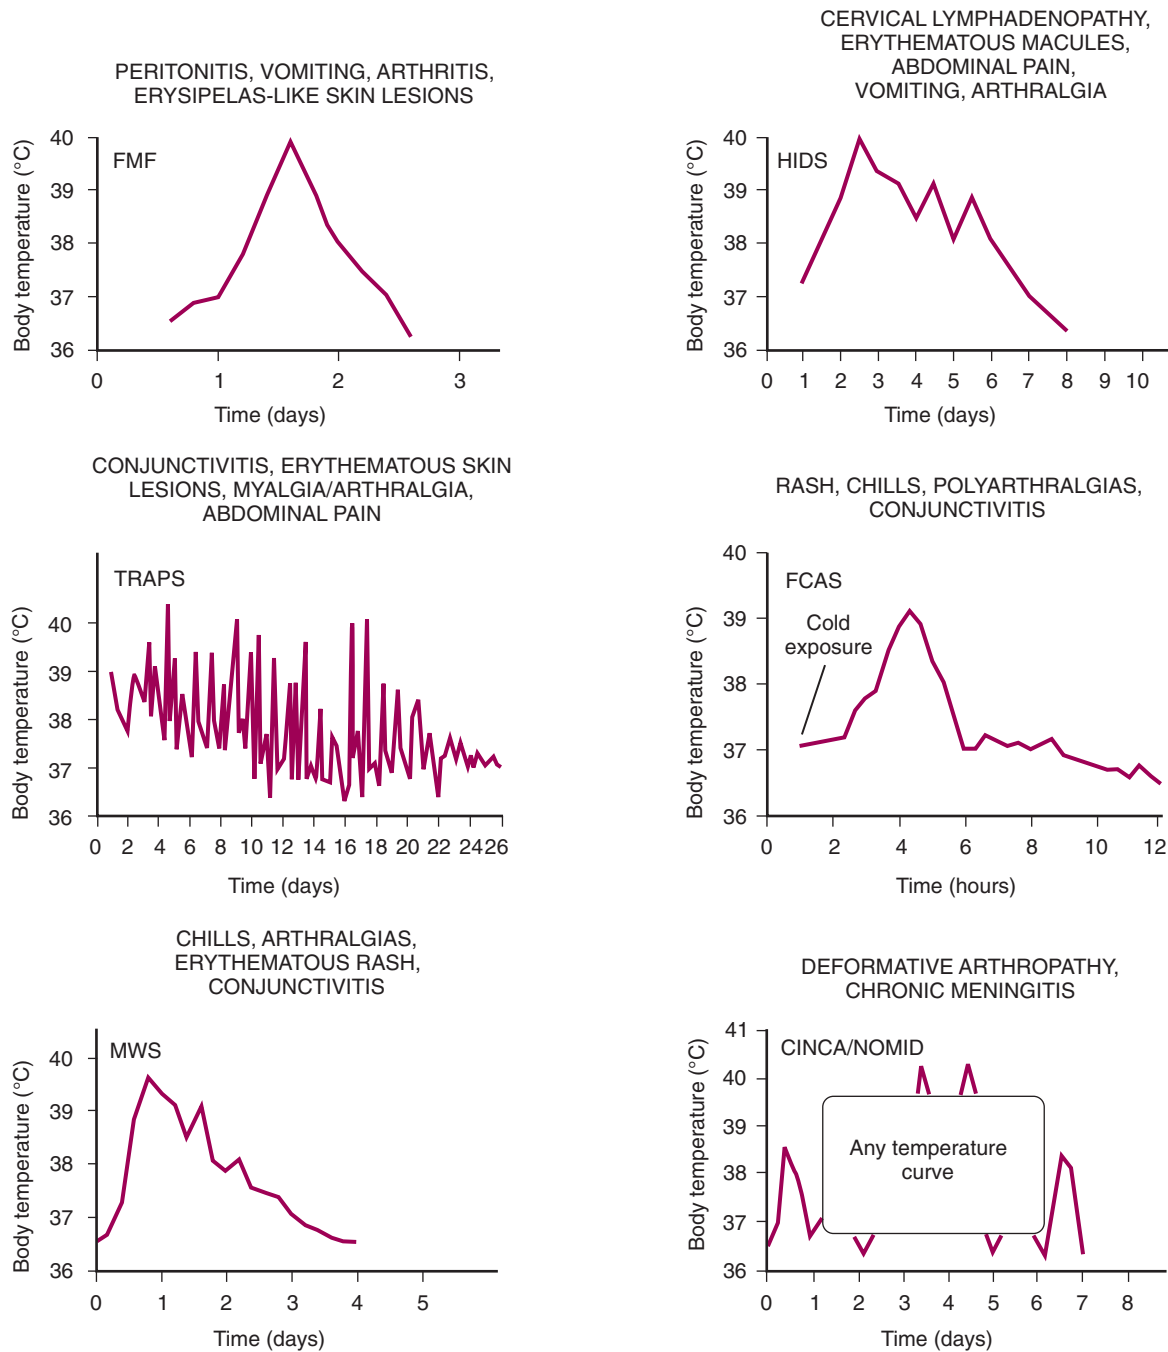

Figure 97-1 Characteristic patterns of body temperature during inflammatory attacks in the familial autoinflammatory syndromes. Interindividual variability for each syndrome is considerable, and even for the individual patient, the fever pattern may vary greatly from episode to episode. Note the different time scales on the x-axes. CINCA/NOMID, chronic infantile neurologic cutaneous and articular syndrome/neonatal-onset multisystemic inflammatory disease; FCAS, familial cold autoinflammatory syndrome; HIDS, hyper-IgD syndrome; MWS, Muckle-Wells syndrome; TRAPS, tumor necrosis factor receptor–associated periodic syndrome.

FAMILIAL MEDITERRANEAN FEVER

Epidemiology

FMF (Mendelian inheritance in men [MIM] 249100) is the most prevalent disorder among the hereditary autoinflammatory syndromes, with more than 10,000 patients affected worldwide. It occurs primarily in people originating from the Mediterranean basin including Armenians, Sephardic

Jews, Arabs, and Turks. FMF is an autosomal recessively inherited disorder. Most families reported with an apparent autosomal dominant inheritance pattern of FMF⁶ represent examples of pseudodominant inheritance owing to consanguinity combined with the high carrier frequency of FMF mutations in certain populations^{6,8}; however, at least three families studied do seem to show a true dominant inheritance, even after extensive genetic analysis.⁸

Table 97-2 Differential Diagnosis of Periodic Fever

1. Hereditary (see Table 97-1)
2. Nonhereditary
a. Infectious
i. Hidden infectious focus (e.g., aortoenteric fistula, Caroli's disease)
ii. Recurrent reinfection (e.g., chronic meningococcemia, host defense defect)
iii. Specific infection (e.g., Whipple's disease, malaria)
b. Noninfectious inflammatory disorder, e.g.:
i. Adult-onset Still's disease
ii. Juvenile chronic rheumatoid arthritis
iii. Periodic fever, aphthous stomatitis, pharyngitis, and adenitis
iv. Schnitzler syndrome
v. Behçet's syndrome
vi. Crohn's disease
vii. Sarcoidosis
viii. Extrinsic alveolitis
ix. Humidifier lung, polymer fume fever
c. Neoplastic
i. Lymphoma (e.g., Hodgkin's disease, angioimmunoblastic lymphoma)
ii. Solid tumor (e.g., pheochromocytoma, myxoma, colon carcinoma)
d. Vascular (e.g., recurrent pulmonary embolism)
e. Hypothalamic
f. Psychogenic periodic fever
g. Factitious or fraudulent

Etiology

In 1997 two groups independently traced the genetic background of FMF to a hitherto unknown gene on the short arm of chromosome 16, dubbed the MEditerranean FeVer (MEFV) gene.^{9,10} At least 80 disease-linked mutations in the MEFV gene have been described so far, most of which are clustered in the tenth exon of this gene (for details see the online mutation database at <http://fmf.igh.cnrs.fr/infervers/>). Most are missense mutations that produce a single amino acid change in the protein (Figure 97-3). There are six common mutations, accounting for almost 99% of all FMF chromosomes: M694V (occurring in 20% to 65% of cases, depending on the population examined¹¹), V726A (in 7% to 35%), M680I, M694I, V694I, and E148Q. For the first three mutations mentioned here, a founder effect has been established,¹⁰ pointing to common ancestors at least 2500 years ago. The high frequency of the mutated MEFV gene in more than one Middle Eastern population has led to the hypothesis that heterozygous carriers have an as-yet-unknown advantage, possibly a heightened (inflammatory) resistance to an as-yet-unidentified endemic pathogen of the Mediterranean basin.¹⁰ In about 30% of patients, only one or no mutations in the MEFV gene can be detected; the etiology in these patients still needs to be determined.

Pathogenesis

The MEFV gene encodes for a protein of 781 amino acids, known as *pyrin* or *marenostri*n. Pyrin is expressed as a cytoplasmic protein in mature monocytes in association with

microtubules¹² but is predominantly found in the nucleus in granulocytes, dendritic cells, and synovial fibroblasts.¹³ The expression of pyrin is induced by inflammatory mediators such as interferon- α and tumor necrosis factor (TNF).¹⁴ The pyrin domain is shared by many proteins involved in apoptosis and inflammation and is a member of the death-domain superfamily that includes death domains, death-effector domains, and caspase-recruitment domains. Pyrin binds specifically to other proteins that contain a pyrin domain, which include the adapter protein “apoptosis-associated specklike-like protein with a CARD” (ASC).

The proinflammatory cytokine interleukin (IL)-1 β is central in the pathogenesis of FMF. This cytokine is expressed as an inactive precursor, which is cleaved by caspase-1 to yield the active IL-1 β . Caspase-1 itself first needs to be activated through the interaction with a protein complex termed an *inflammasome*. Several inflammasomes have been described so far. The major inflammasome complex involved in the activation of caspase-1 and IL-1 β is the cryopyrin or NLRP3 inflammasome.^{15,16} Two hypotheses have been proposed regarding the effect of pyrin on IL-1 β processing. The “sequestration hypothesis” holds that pyrin has an inhibitory effect on caspase-1–mediated activation of IL-1 β , through its prevention of the formation of the cryopyrin inflammasome by competitive binding of the adapter protein ASC and procaspase-1 and binding caspase-1.^{17,18} Under this hypothesis, FMF mutations are thought to interfere with the inhibiting interactions of pyrin, resulting in decreased regulation of IL-1 β activation.¹⁸ The second hypothesis, proposed by Yu and colleagues,¹⁹ suggests that pyrin can form its own specific inflammasome for activation of IL-1 β , although not all the components of this proposed inflammasome have been specified so far. The FMF mutations would increase the sensitivity of this putative pyrin inflammasome. Apart from its role in regulation of IL-1 β , there is also conflicting evidence for the effect of pyrin on regulation of nuclear factor κ B (NF κ B) or apoptosis, varying from inhibition to stimulation.¹

Clinical Features

In approximately 90% of FMF patients, symptoms start before age 20 years.²⁰ The inflammatory attacks of FMF usually last 1 to 3 days. The frequency can vary widely; 2 to 4 weeks is the most common interval (see Figure 97-1). Symptoms of serositis (i.e., peritonitis, pleuritis, synovitis) are the main feature of FMF attacks, usually accompanied by fever. Abdominal pain of 1 or 2 days' duration occurs in 95% of patients, varying in severity from severe peritonitis resembling an acute abdomen to only mild abdominal pain without overt peritonitis.²¹ Arthritis (rarely destructive) is often confined to one large joint such as the knee, ankle, or wrist and may be the only symptom. Chest pain resulting from pleuritis is usually unilateral and associated with a friction rub or transient pleural effusion. Skin involvement occurs in approximately 30% of patients, most often as erysipelas-like skin lesions on the shins or feet (Figure 97-4).²² Other, more uncommon, symptoms are pericarditis, occurring in less than 1%²³; acute scrotal swelling and tenderness²⁴; aseptic meningitis; and severe protracted myalgia, especially of the legs.

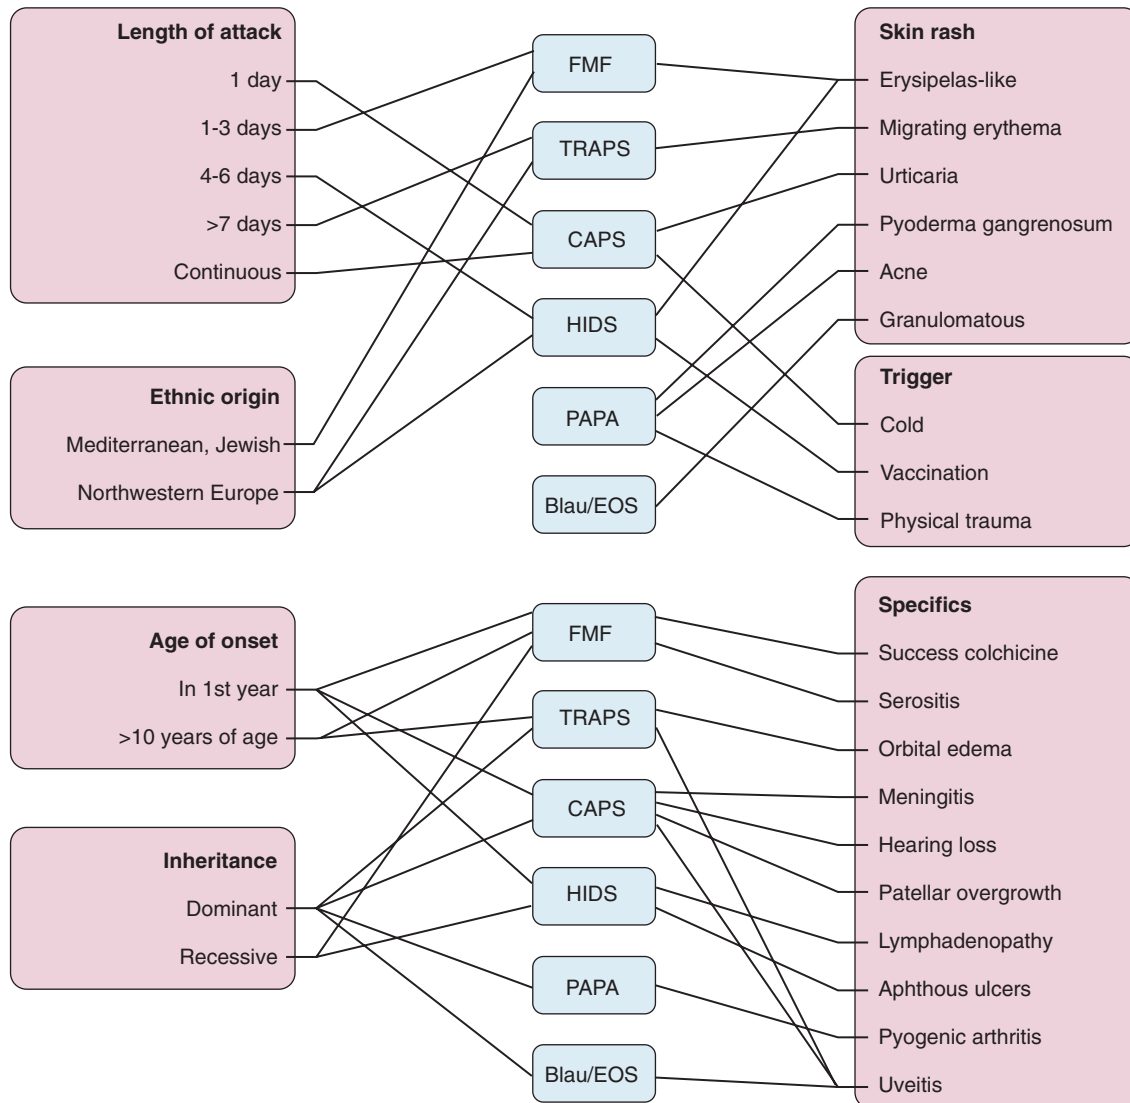

Figure 97-2 Differential diagnosis of the familial autoinflammatory syndromes. First exclude other, more common causes of fever and inflammation in the patient. When a familial autoinflammatory syndrome seems likely, check the clinical characteristics found in the patient on the right and left of the diagram, and assign one point to each syndrome that is linked to these characteristics by a line (one characteristic could lead to or point to more than one syndrome). The final combined score assigns a rank for the likelihood of the disorders in this patient and offers help in deciding on the correct subsequent diagnostic tests. This algorithm is not evidence based but is solely derived from expert opinion. CAPS, cryopyrin-associated periodic syndrome; EOS, early-onset sarcoidosis; FMF, familial Mediterranean fever; HIDS, hyper-IgD syndrome; PAPA, pyogenic sterile arthritis, pyoderma gangrenosum, and acne; TRAPS, tumor necrosis factor receptor–associated periodic syndrome.

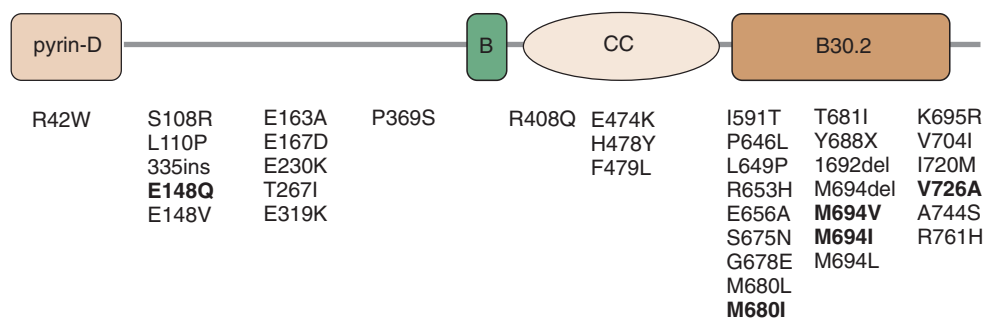

Figure 97-3 Schematic representation of pyrin (marenostrin) protein, with four conserved domains including a pyrin domain, a B-box (B), coiled-coil domain (CC), and a B30.2 domain. Indicated are mutations as found in familial Mediterranean fever, with the five most common missense mutations in bold type. For complete listing of all currently known mutations, see INFEVERS website: <http://fmf.igh.cnrs.fr/infevers/>.

Diagnosis and Diagnostic Tests

FMF is still primarily a clinical diagnosis. There is a set of validated diagnostic criteria with a reported sensitivity and specificity of 96% to 99% (Table 97-3).²⁵ These criteria were validated in a population with a high prevalence of FMF and low prevalence of the other autoinflammatory disorders, however, and the ethnic origin of the patient needs to be taken into account. In molecular diagnostic testing, genetic laboratories usually screen for the five most common mutations and rare mutations are missed. *MEFV* mutations occur on both alleles in only 70% of typical cases,²⁶ whereas in the remaining 30%, only one or no mutation can be detected, even after sequencing. There is also evidence of reduced penetrance. Despite these limitations, molecular testing can be used as a confirmatory test. Whether or not the results are positive, treatment with colchicine is warranted in symptomatic cases of fitting ethnic origin fulfilling the diagnostic criteria.^{27,28} No specific biologic marker is available to distinguish an inflammatory FMF attack from an infectious fever or appendicitis. During an inflammatory

attack, there is an acute-phase response, which includes elevation of SAA, CRP, and plasma fibrinogen and polymorphonuclear leukocytosis. Proteinuria in patients with FMF is highly suggestive of renal amyloidosis.

Treatment

Colchicine is the first-line treatment for patients with FMF. Colchicine prevents inflammatory attacks completely in 60% to 75% of patients, and it significantly reduces the number of attacks in an additional 20% to 30%.²⁹ The average dose in adults is 1 mg daily, but this may be increased to 3 mg in cases in which no response is seen at the lower dose. This regimen is usually well tolerated; gastrointestinal side effects including diarrhea and abdominal pain generally resolve with dose reduction. More serious side effects such as myopathy, neuropathy, and leukopenia are rare and occur primarily in patients with renal or liver impairment. During a fever attack, oral or intramuscular nonsteroidal anti-inflammatory drugs (NSAIDs) can be used for pain relief. Glucocorticoids have limited efficacy.

Compliance with colchicine use is important because colchicine has been shown to prevent the occurrence of amyloidosis. Since the introduction of colchicine therapy, the incidence of amyloidosis in FMF has decreased dramatically, whereas in areas with a high prevalence of FMF where colchicine is not routinely available, such as Armenia, amyloidosis is still common. Colchicine's principal effect at the cellular level is to depolymerize microtubules by interacting with tubulin, inhibiting motility and exocytosis of intracellular granules. It has a powerful antimitotic effect, causing metaphase arrest. It has been speculated, in cases of infertility in patients treated with colchicine, that this medication causes azoospermia. Colchicine does not have a significant adverse effect on sperm production or function, however.³⁰ Unfounded fear of teratogenic effects of colchicine often wrongly leads to cessation of this drug in young women who want to get pregnant, with a subsequent increased frequency and severity of attacks, which enhances problems with fertility and pregnancy. Colchicine has proved to be safe, even in early pregnancy, and treatment should not be interrupted for this reason.^{31,32} It can also be used while breastfeeding.²⁹

In about 5% to 10% of patients, FMF is refractory to colchicine use. Lidar and colleagues³³ used parenteral colchicine in such refractory cases, but this can be toxic. More recently, the IL-1 β inhibitor anakinra has been shown to be effective in several case reports and series.³⁴⁻³⁸

Outcome

Recurrent attacks of peritonitis may lead to intra-abdominal or pelvic adhesions, resulting in complications such as small bowel obstruction. Another serious long-term complication of FMF is amyloid A (AA) amyloidosis. This amyloidosis is primarily found in the kidneys, resulting in renal failure, but can also occur in the gastrointestinal tract, liver, and spleen, and eventually in the heart, testes, and thyroid. The prevalence of amyloidosis varies, especially depending on the ethnic origin, but it is high in untreated patients. It is common among Sephardic Jews but rare in Ashkenazi Jews.³⁹

Table 97-3 Diagnostic Criteria for Familial Mediterranean Fever*

Major Criteria
Typical attacks [†] with peritonitis (generalized)
Typical attacks with pleuritis (unilateral) or pericarditis
Typical attacks with monoarthritis (hip, knee, ankle)
Typical attacks with fever alone
Incomplete abdominal attack
Minor Criteria
Incomplete attacks [‡] involving chest pain
Incomplete attacks involving monoarthritis
Exertional leg pain
Favorable response to colchicine

*Requirements for diagnosis of familial Mediterranean fever are ≥ 1 major criteria or ≥ 2 minor criteria.

[†]Typical attacks are defined as recurrent (≥ 3 of the same type), febrile ($\geq 38^{\circ}\text{C}$), and short (lasting between 12 hours and 3 days).

[‡]Incomplete attacks are defined as painful and recurrent attacks not fulfilling the criteria for a typical attack.

From Livneh A, Langevitz P, Zemer D, et al: Criteria for the diagnosis of familial Mediterranean fever, *Arthritis Rheum* 40:1879–1885, 1997.

For a variety of reasons including peritoneal adhesions and ovulatory dysfunction, subfertility in women is common.³¹ In men, subfertility secondary to azoospermia (sometimes secondary to testicular amyloidosis) or impairment of sperm penetration has been found.²⁰

HYPER-IMMUNOGLOBULIN D SYNDROME (MEVALONATE KINASE DEFICIENCY)

Epidemiology

Hyper-IgD syndrome (HIDS) (MIM 260920), also known as *mevalonate kinase deficiency*, is an autosomal recessively inherited disorder, but it is far less prevalent than FMF. The International Hyper-IgD Syndrome Registry, based in Nijmegen, the Netherlands, in which clinical information is collected from physicians worldwide, currently holds data on approximately 220 patients. Approximately 75% of these patients are from Western Europe, and 50% are from the Netherlands and France.⁴⁰ Most HIDS patients are of Caucasian origin. These observations can be explained partly by a founder effect.⁴¹ In the Netherlands, the carrier frequency of the most common mevalonate kinase mutation is 1 : 153.⁴² Men and women are affected in equal numbers.⁴⁰

Etiology

HIDS is caused by mutations in the gene encoding for the enzyme mevalonate kinase, located on the long arm of chromosome 12 (for details, see the online mutation database available at <http://fmf.igh.cnrs.fr/infevers/>).⁴³⁻⁴⁵ Patients with classic HIDS are most often compound heterozygotes for two missense mutations (Figure 97-5). Two mutations (V377I and I268T) account for more than 85% of the patients described to date.⁴⁰

The term *variant type HIDS*, which we proposed for patients with an autoinflammatory disease and high immunoglobulin (Ig)D without mevalonate kinase deficiency,⁴⁵ has been largely abandoned. Many patients with fever syndromes have a raised IgD and this subclass is heterogeneous. It seems more useful to designate these patients as “autoinflammatory disease not otherwise specified” to indicate that a more specific diagnosis may still be found in the future.

Pathogenesis

Mevalonate kinase is part of the isoprenoid pathway; it is the step after 3-hydroxy-3-methyl-glutaryl-coenzyme A (HMG-CoA) reductase, phosphorylating mevalonic acid. The isoprenoid pathway has many diverse end products that include cholesterol, dolichol, and ubiquinone, and it leads to isoprenylation of proteins, with a post-translational modification directing these proteins such as Rho and Ras to the cell membrane.⁴⁶

HIDS mutations lead to a constantly diminished activity of mevalonate kinase to about 5% to 15% of normal levels, and these levels decrease further during a fever attack.⁴⁷ Because of this reduced enzyme activity, the substrate mevalonic acid accumulates in serum and urine. Higher levels are found during the episodes of fever. There does not seem to be a dramatic shortage of any specific end product; concentrations of cholesterol, ubiquinone, and dolichol in patients are normal to slightly decreased.¹

Another syndrome was already linked to mutations in the mevalonate kinase gene before the discovery of HIDS⁴⁸—classic mevalonic aciduria. Patients with mevalonic aciduria carry specific mutations that cause a more severe reduction of mevalonate kinase enzyme activity, reducing it to undetectable levels. These patients constantly produce large amounts of mevalonic acid and often have more than 1000 times as much mevalonic acid in their urine than do HIDS patients.⁴⁹ Patients with mevalonic aciduria also have a more severe phenotype. Classic mevalonic aciduria and HIDS seem to be two extremes of a continuous spectrum of disease related to mevalonate kinase deficiency.⁵⁰

The pathogenetic link between mevalonate kinase deficiency and inflammation is still unclear, but there is increasing evidence for a connection between the isoprenoid pathway and inflammation. Inhibition of the isoprenoid pathway by statins, the inhibitors of HMG-CoA reductase (the enzymatic step before that of mevalonate kinase), can have anti-inflammatory effects, ranging from increased apoptosis of inflammatory cells to reduction of expression of cytokines.^{51,52} In other settings, statins seem to be proinflammatory, most notably in a study in which stimulation with *Mycobacterium tuberculosis* or mitogens in combination with statins increased caspase-1 activation and IL-1 β secretion by monocytes, through a decrease of geraniolgeraniol.¹⁵ The ex vivo production of IL-1 β is increased in HIDS,^{53,54}

Figure 97-5 Mevalonate kinase, with four conserved domains represented by colored boxes. Indicated are missense mutations, nonsense mutations, and two deletions, which have been identified in mevalonate kinase deficiency. In bold are mutations found in mevalonic aciduria patients; in bold and italic are mutations found in classic hyper-IgD syndrome and mevalonic aciduria. For complete listing of all currently known mutations, see INFEVERS website: <http://fmf.igh.cnrs.fr/infevers/>.

whereas treatment with the IL-1 blocker anakinra is beneficial.^{55,56} Current evidence points to a link between the mevalonate pathway and IL-1 through alterations of isoprenylation of the small GTPase Rac1, phosphoinositide 3-kinase (PI3K), and protein kinase B (PKB).⁵⁷ A defect in apoptosis may also contribute to the pathogenesis of HIDS. Lymphocytes from HIDS patients (who had no fever at the time of blood sampling) showed a decrease in apoptosis when stimulated with anisomycin, which was not found in patients with TNF receptor–associated periodic syndrome (TRAPS) or FMF patients.⁵⁸ Such a decrease in apoptosis would result in increased survival of lymphocytes and may delay the resolution of the inflammatory response. An ordinarily innocuous stimulus in HIDS patients would more easily lead to a full-blown fever episode.

The cause of the characteristic high serum concentrations of IgD in this syndrome, which have led to its name, is still unexplained.

Clinical Features

Ninety percent of patients with HIDS experience their first fever episode in the first year of life,⁴⁰ and these episodes become most frequent in childhood and adolescence. The high fevers may lead to seizures, especially in young children. Vaccination, minor trauma, surgery, and physical or emotional stress are factors that provoke a fever episode, although often a triggering factor is not obvious.⁴⁰ The fevers often begin with cold chills and a sharp increase in body temperature. They are almost always accompanied by cervical lymphadenopathy and abdominal pain with vomiting and diarrhea. Other frequent symptoms are headache, myalgia, and arthralgia. Apart from the lymphadenopathy, physical signs frequently consist of splenomegaly and a skin rash with erythematous macules and papules (Figure 97-6) or petechiae (Figure 97-7).⁴⁰ Sometimes there are also signs of frank arthritis (principally large joints) and hepatomegaly. About 40% of patients report painful aphthous ulcers

Figure 97-6 Facial erythematous macules and papules in a hyper-IgD syndrome patient during an attack.

Figure 97-7 Petechiae on the leg of a hyper-IgD syndrome patient during a febrile attack.

in the mouth, vagina, or scrotum (Figure 97-8). The fever disappears spontaneously after 3 to 5 days, although it may take longer before the symptoms in joints or skin disappear completely. These inflammatory attacks occur, on average, once every 4 to 6 weeks, although this may vary from patient to patient or in an individual patient.

Patients with mevalonic aciduria, the metabolic disorder that is also caused by mevalonate kinase gene mutations, experience similar but more severe inflammatory episodes as HIDS patients. In addition, these patients suffer from psychomotor retardation, ataxia, failure to thrive, cataracts, and dysmorphic facies. Patients with classic mevalonic aciduria usually die in early childhood.⁴⁹ An intermediary clinical phenotype between classic mevalonic aciduria and HIDS has been described.⁵⁰

Figure 97-8 Aphthous ulceration detected on the tongue of a patient with hyper-IgD syndrome. (Courtesy Dr. K. Anttila, North Carelian Central Hospital, Joensuu, Finland.)

Table 97-4 Diagnostic Indicators of Hyper-IgD Syndrome

At Time of Attacks
Elevated erythrocyte sedimentation rate and leukocytosis
Abrupt onset of fever ($\geq 38.5^{\circ}\text{C}$)
Recurrent attacks
Lymphadenopathy (especially cervical)
Abdominal distress (e.g., vomiting, diarrhea, pain)
Skin manifestations (e.g., erythematous macules and papules)
Arthralgias and arthritis
Splenomegaly
Constantly Present
Elevated IgD ($\geq 100\text{ U/mL}$) measured on 2 occasions at least 1 mo apart*
Elevated IgA ($\geq 2.6\text{ g/L}$)
Specific Features
Mutations in mevalonate kinase gene
Decreased mevalonate kinase enzyme activity

*Extremely high serum concentrations of IgD are characteristic but not obligatory.

Diagnosis and Diagnostic Tests

HIDS is diagnosed on the basis of a combination of characteristic clinical findings and continuously elevated IgD concentrations ($>100\text{ IU/mL}$) (Table 97-4). There are numerous caveats concerning IgD serum concentration, however: Values may be normal in young patients (especially patients younger than 3 years old),⁵⁹ persistently normal levels have been reported in a few patients with HIDS,⁴³ and patients with other familial autoinflammatory syndromes may also have elevated IgD concentrations, although these are usually only slightly elevated. More than 80% of HIDS patients combine a high concentration of IgD with high IgA levels.^{59,60} During fever attacks, a brisk acute-phase response is observed including leukocytosis, high levels of SAA and CRP, and activation of the cytokine network.^{53,61}

The diagnosis of HIDS can be confirmed by DNA analysis of the mevalonate kinase gene. The best approach is to start with screening for the two most prevalent mutations, V377I and I268T. If this screening is negative, but the clinical suspicion remains high, sequencing of the entire gene can be considered. A good alternative is the measurement of urinary mevalonic acid concentrations during an attack, which are slightly elevated. Gas chromatography–mass spectroscopy is necessary to detect this slight increase, however.⁶² The measurement of mevalonate kinase enzyme activity is complicated and time-consuming and should be reserved for research purposes.

Treatment

There is no established treatment regimen for HIDS. Anakinra is effective in reducing disease severity in a number of case reports^{55,56,63–65} and is currently the most promising therapy. A double-blind, placebo-controlled, crossover trial of the HMG-CoA reductase inhibitor simvastatin showed a beneficial effect of this drug, with a reduction in number of days of illness in five out of six patients⁶⁶; however, in clinical practice the beneficial effect is not

impressive. Favorable preliminary experience with the TNF antagonist etanercept has been reported.^{55,67,68}

Some individual patients have been reported to have benefited from treatment with corticosteroids, colchicine, intravenous immunoglobulin, or cyclosporine, but these results have not been repeated in most patients.⁴⁰ Thalidomide did not have an effect on disease activity in a placebo-controlled trial.⁶⁹

Outcome

The long-term outcome in HIDS is relatively benign in most patients. In some patients, the fever episodes occur less frequently and become less severe later in life, starting from late adolescence.⁴⁰ Joint destruction is rare, but abdominal adhesions are seen, resulting from repeated abdominal inflammation or (unnecessary) diagnostic laparotomy because of suspected acute abdomen.

Until more recently, no cases of amyloidosis had been seen in HIDS patients since its first description in 1984. Since 2004, four HIDS patients 19 to 27 years old have been reported who developed renal failure because of AA amyloidosis.^{40,70–72} Regular screening for proteinuria also may be advisable in HIDS patients, especially patients with frequent and severe fever episodes.

TUMOR NECROSIS FACTOR RECEPTOR-ASSOCIATED PERIODIC SYNDROME

Epidemiology

TRAPS (MIM 142680) has an autosomal dominant inheritance pattern. It was originally described in a large family from Irish and Scottish descent as “familial Hibernian fever.”⁷³ It is found primarily in patients from northwestern Europe but also has been described in families from Australia, Mexico, Puerto Rico, Portugal, and the Czech Republic.⁷⁴ Any ethnic group may be affected. Other abandoned nomenclature for this syndrome includes “autosomal dominant familial periodic fever”⁷⁵ and “familial perireticular amyloidosis.”⁷⁶

Etiology

Mutations are found in the gene for the type I TNF receptor (*TNFRSF1A*), which is located on the short arm of chromosome 12.⁴ These are mainly single-nucleotide missense substitutions, located in exons 2, 3, and 4, which encode for the extracellular domain of *TNFRSF1A*. Many of these mutations disrupt one of the highly conserved cysteine residues involved in extracellular disulfide bonds of the 55-kD type I TNF receptor protein (Figure 97-9) (for details, see the online mutation database available at <http://fmf.igh.cnrs.fr/infevers/>).⁷⁷

There are some general genotype-phenotype correlations, especially when mutations are grouped in cysteine and noncysteine mutations. Noncysteine mutations have, overall, a lower penetrance than cysteine mutations, and amyloidosis is seen far more often in association with cysteine mutations.⁷⁸ Two missense mutations in *TNFRSF1A*, P46L and R92Q, have a particularly low penetrance and

Figure 97-9 Schematic representation of the tumor necrosis factor (TNF) receptor type 1 protein (TNFRSF1A), depicting mutations found in TNF receptor–associated periodic syndrome up to this time (except for one intron mutation affecting a splice site). Mutations disrupting cysteine residues are in boldface type. For complete listing of all currently known mutations, see INFEVERS website: <http://fmf.igh.cnrs.fr/infevers/>.

are found in approximately 1% to 10% of control chromosomes.⁷⁸⁻⁸⁰ R92Q has been observed in higher prevalence in a group of patients with arthritis. It is thought that the clinical manifestations of patients with an R92Q mutation depend on other so-far-unidentified modifying genes, environmental factors, or both.^{77,78}

Pathogenesis

TNF is a pleiotropic molecule, which induces cytokine secretion, activation of leukocytes, fever, and cachexia. Activation of the TNF receptor by TNF causes cleavage and shedding of its extracellular part into the circulation, where it acts as an inhibitor of TNF. However, TRAPS-associated mutations in the TNF receptor lead not to an increase but rather to a loss of TNF-signaling function including less binding of TNF,^{81,82} less cell surface expression,⁸²⁻⁸⁵ and decreased TNF-induced NF κ B-activation.^{84,86,87} The mutated *TNFRSF1A* is retained intracellularly, pooled in the endoplasmic reticulum.^{82,83,87,88} Mutant *TNFR1* cannot associate with the wild-type version but can form aggregates by self-interaction.^{82,83} This cytoplasmic receptor aggregation results in ligand-independent signaling.^{87,89} Mitochondrial-derived reactive oxygen species appear to mediate this effect.⁹⁰ This new hypothesis also might offer an explanation for the observation that blocking IL-1 β works better in some TRAPS patients than blocking TNF.^{87,91}

An alternative hypothesis, the “shedding hypothesis,” was postulated on the finding of reduced shedding, which leads to prolonged TNF signaling and uncontrolled inflammation. Not all TRAPS mutations cause decreased shedding, however, and although serum concentrations of the shed soluble *TNFRSF1A* in TRAPS patients during periods without symptoms are often found to be significantly reduced compared with normal subjects, this is not always the case.¹ The hypothesis of reduced shedding, although attractive by its simplicity, is not supported as the sole cause of the fever attacks in TRAPS, and additional mechanisms seem to be at work.

Clinical Features

The clinical features can vary much more between individual TRAPS patients than is generally seen in FMF or HIDS.^{74,77} The age of onset can vary, even within the same family, with a documented range of 2 weeks to 53 years old.^{74,92} There is also a large variation in duration and frequency of the fever episodes in TRAPS. On average, attacks last 3 to 4 weeks and recur two to six times each year, but episodes also may be limited to a few days (see Figure 97-1). Although the index patient, through whom the diagnosis is made, often displays well-defined inflammatory attacks, affected family members may have less typical symptoms such as episodic mild arthritis.

During inflammatory attacks, a high, spiking fever can be accompanied by skin lesions, myalgia and arthralgia, abdominal distress, and ocular symptoms. The most common cutaneous manifestation is a centrifugal, migratory, erythematous patch, which may overlie a local area of myalgia (Figure 97-10),⁹³ but urticarial plaques also may be seen.

Figure 97-10 Migrating erythematous rash during a tumor necrosis factor receptor–associated periodic syndrome attack. (Courtesy Dr. T. Fiselier, University Medical Center St. Radboud, Nijmegen, The Netherlands.)

Myalgia is often located primarily in the muscles of the thighs, but it may migrate during the fever episode, affecting all of the limbs and the torso, face, and neck. Arthralgia primarily affects large joints including hips, knees, and ankles. Frank synovitis is rarer, and when it does occur it is nonerosive, asymmetric, and monoarticular.⁷⁴ Abdominal pain occurs in 92% of TRAPS patients during inflammatory attacks; other gastrointestinal symptoms often seen include vomiting and constipation. Ocular involvement is characteristic in TRAPS, and it may involve conjunctivitis, periorbital edema, or periorbital pain in one or both eyes. Severe uveitis and iritis have been described, and any TRAPS patient with ocular pain should be examined for these complications.^{74,93} Other, less frequently observed symptoms during fever attacks in TRAPS are chest pain, breathlessness, pericarditis, and testicular and scrotal pain, which may be caused by inflammation of the tunica vaginalis. One case report described a patient who presented with psychosis without fever.⁹⁴ It has been suggested from observation in one of the first families with TRAPS that this disorder is associated with an increased incidence of indirect inguinal hernias,⁹⁵ but this has not been shown in other patients. Lymphadenopathy is rare in TRAPS.

Diagnosis and Diagnostic Tests

As in the other familial autoinflammatory syndromes, laboratory investigations during inflammatory attacks show a clear acute-phase response, and even in between fever attacks, such an inflammatory response may be measured. The IgD level may be elevated, but the value is almost always less than 100 IU/mL.^{92,95}

Hull and colleagues⁷⁴ proposed a set of clinical diagnostic criteria for TRAPS (Table 97-5). These criteria are not validated by epidemiologic measures, but they may be used as a first step in evaluation of patients. TRAPS is ultimately a genetic diagnosis, defined by a missense mutation in the gene for *TNFRSF1A*. Clinical penetrance of TRAPS mutations is not 100%, however, even for cysteine mutations, and asymptomatic carriers are common. Also, the finding of an R92Q or P46L variant in this gene would pose a difficulty. Because they have many characteristics of a

polymorphism rather than a direct disease-causing mutation (see etiology), it is debatable whether such a finding should lead to a diagnosis of TRAPS.

Treatment

In mild cases of TRAPS, NSAIDs are often sufficient. NSAIDs and glucocorticoids in high doses (>20 mg/day of oral prednisone) alleviate the symptoms of fever and inflammation in most TRAPS patients, although they do not alter the frequency of attacks. They can be used beneficially at times of attack, and glucocorticoids usually can be tapered in the course of 1 or 2 weeks, as tolerated. There is no response to colchicine or immunosuppressive drugs such as azathioprine, cyclosporine, thalidomide, or cyclophosphamide.⁷⁴

Anti-TNF and anti-IL-1 biologic therapy is much more effective in reducing symptoms. Use of etanercept, a fusion product of TNFRSF1B (the receptor that is not defective) has been partially successful.^{74,78,96,97} A study with twice-weekly administration of etanercept (25 mg for adults or 0.4 mg/kg for children) in nine TRAPS patients with various mutations revealed an overall 66% response rate as determined by decreased number of attacks over a 6-month period.⁷⁴ Another study with the same dosage of etanercept for 24 weeks in seven TRAPS patients also showed a clear beneficial effect without serious adverse events.⁹⁶ A similar regimen of etanercept reversed the nephrotic syndrome in a patient with amyloidosis.⁹⁸

Drewe and colleagues⁹⁹ described one patient whose symptoms were resistant to administration of etanercept, who responded favorably to use of oral sirolimus (4 to 6 mg daily). Infliximab, a monoclonal antibody against TNF, has been shown to be less effective than etanercept in TRAPS and seems to cause increased symptoms.^{96,99,100} Intravenous infusion of a synthetic TNFRSF1A fusion protein was tried in one patient by Drewe and colleagues,⁹⁶ but this seemed to provoke a severe attack.

Blocking IL-1 β with anakinra is even more effective than blocking TNF in several case reports and case series.^{91,101-103}

Outcome

Reactive AA amyloidosis is the principal systemic complication of TRAPS. It occurs in about 15% to 25% of patients^{78,104} and generally leads to renal impairment. Amyloidosis in a patient with TRAPS places other affected family members at high risk for this complication. It is principally associated with *TNFRSF1A* mutations affecting cysteine residues.⁷⁸ Because proteinuria is the initial manifestation of renal amyloidosis, it is advisable to screen urine samples from TRAPS patients regularly by dipstick examination, especially affected family members of a TRAPS patient with amyloidosis.

Table 97-5 Diagnostic Indicators of Tumor Necrosis Factor Receptor–Associated Periodic Syndrome

1. Recurrent episodes of inflammatory symptoms spanning >6 mo duration (several symptoms generally occur simultaneously)
 - a. Fever
 - b. Abdominal pain
 - c. Myalgia (migratory)
 - d. Rash (erythematous macular rash occurs with myalgia)
 - e. Conjunctivitis or periorbital edema
 - f. Chest pain
 - g. Arthralgia or monoarticular synovitis
2. Episodes last >5 days on average (although variable)
3. Responsive to glucocorticosteroids but not colchicine
4. Affects family members in autosomal dominant pattern (although may not always be present)
5. Any ethnicity may be affected

CRYOPYRIN-ASSOCIATED PERIODIC SYNDROME

Cryopyrin-associated periodic syndrome (CAPS) encompasses three clinical syndromes that all have been traced to

mutations in one common gene: Muckle-Wells syndrome (MWS), familial cold autoinflammatory syndrome (FCAS), and chronic infantile neurologic cutaneous and articular syndrome (CINCA), also known as *neonatal-onset multisystemic inflammatory disease* (NOMID). After the recognition of the genetic defect, it became clear that there is considerable overlap among these three disorders.¹⁰⁵ FCAS, MWS, and CINCA/NOMID might represent a spectrum of disease, with FCAS the mildest and CINCA the most severe form. Given their common genotype, they are discussed under one heading here, but clinical features and outcomes are dealt with separately.

Epidemiology

All three syndromes are rare, autosomal dominantly inherited syndromes. Most articles on FCAS, first described in 1940, describe large families from Europe and North America with extensive pedigrees, but sporadic cases have been described. There seems to be a founder effect in American families of Northern European extraction.¹⁰⁶ MWS was first described in 1962 and has since been described in large families, although it does occur in isolated cases and small nuclear families. CINCA is rare, and, to date, some 70 cases and only a few families have been described.

Etiology

The first indications that MWS and FCAS are allelic stem from early linkage studies showing that FCAS and MWS were linked to the same region on the long arm of chromosome 1 (1q44).^{107,108} In 2001, the gene for FCAS and MWS was identified. In a large-scale, positional cloning effort using three families with FCAS and one family with MWS, missense mutations in a new gene were found.¹⁰⁹ This gene, *CIAS1*, encodes for a protein denoted cryopyrin at discovery, but now by consensus known as NLRP3 (other names that have been used are NALP3 and PYPAF). Later studies showed that *CIAS1* mutations were also associated with CINCA.^{110,111} Practically all mutations are missense mutations found in exon 3 of the *CIAS1* gene, which encodes for the NOD domain of NLRP3.¹¹² (Figure 97-11) (for

details, see the online mutation database available at <http://fmf.igh.cnrs.fr/infevers/>).

Pathogenesis

NLRP3 or cryopyrin was a previously unknown protein at the time of the discovery of the mutations involved in these syndromes. Since that time, it has become the focus of numerous studies, which have led to a new concept—the inflammasome.¹¹³ NLRP3 is a member of the nucleotide-binding oligomerization domain–leucine-rich repeat (NOD-LRR) protein family.¹¹⁴ It consists of a pyrin domain (PYD), a NOD (also known as NACHT domain), and a LRR domain. NLRP3 is mainly expressed in monocytes and neutrophils but is also found in human chondrocytes.^{109,111,115}

NLRP3 is thought to be an intracellular sensor of pathogens or danger signals, regulating innate immunity. On stimulation with various ligands, which include bacterial RNA, imidazoquinolone compounds, gram-positive bacterial toxins nigericin and maitotoxin, adenosine triphosphate, and uric acid crystals, NLRP3 forms interactions with adapter proteins ASC and cardinal, which results in a multiprotein complex termed the *NLRP3 inflammasome*. The NLRP3 inflammasome activates caspase-1, which subsequently cleaves pro-IL-1 β to the active IL-1 β .^{116,117}

There is conflicting evidence for a role of NLRP3 in regulation of transcription factor NF κ B.¹ Possibly, the ultimate effect on NF κ B is determined by interaction of multiple proteins. Four more recent publications by independent groups that each developed an NLRP3-deficient mouse showed no effect, however, on NF κ B activation in these mice, whereas they did show a clear deficiency in caspase-1-mediated IL-1 β activation.¹

Monocytes from patients with mutations in the NOD of NLRP3 show increased activation of caspase-1 and subsequently increased release of IL-1 β .^{117,118} The key role of IL-1 β in CAPS is confirmed by the success of treatment with the IL-1 blocker anakinra in all three clinical syndromes (see treatment section).

The exact effect of the NLRP3 mutations is still unclear. An attractive hypothesis involves a possible autoinhibitory loop of NLRP3.¹¹⁸ Mutations in the NOD could interfere

Figure 97-11 Cryopyrin protein, containing an N-terminal pyrin domain, a nucleotide binding site (NACHT), and a leucine-rich repeat (LRR) domain. Indicated are missense mutations identified in patients with familial cold autoinflammatory syndrome (red), Muckle-Wells syndrome (green), or chronic infantile neurologic cutaneous and articular syndrome (blue), and mutations found in common in two or all of these clinical syndromes (black). For complete listing of all currently known mutations, see INFEVERS website: <http://fmf.igh.cnrs.fr/infevers/>.

with this autoinhibitory mechanism of NLRP3, leading to undue and excessive activation of caspase-1 and IL-1 β .¹

Clinical Features and Outcome

Familial Cold Autoinflammatory Syndrome

FCAS (MIM 120100) is characterized by episodes of rash, fever, and arthralgia after generalized exposure to cold (see Figure 97-1). The disease occurs in large families as an autosomal dominant inherited disorder with an almost complete penetrance.¹⁰⁶ The rash usually starts on the exposed extremities and, in most episodes, extends to the remainder of the body. It consists of erythematous macules and plaques (Figures 97-12 and 97-13), urticarial lesions, and sometimes petechiae¹¹⁹ and can cause a burning or itchy sensation. In one case report, FCAS was associated with Raynaud's disease.¹²⁰ In some cases, localized edematous swelling of extremities is reported. Arthralgia, present in 93% of cases, most often affects the hands, knees, and ankles but can also involve feet, wrists, and elbows.¹²¹ Frank arthritis is not

Figure 97-13 Detail of upper leg with fine, confluent, erythematous macules in familial cold autoinflammatory syndrome. (Courtesy Dr. Johnstone, Medical College of Georgia, Augusta, Ga.)

seen. Most patients (84%) also report conjunctivitis during a fever episode. Other symptoms include myalgia, profuse sweating, drowsiness, headache, extreme thirst, and nausea.

A typical feature of FCAS is the requirement of cold exposure to trigger the symptoms. The delay between cold and onset of symptoms varies from 10 minutes to 8 hours.¹²¹ When Hoffman and colleagues¹²² provoked an inflammatory attack in FCAS patients by generalized cold exposure in a cold room, they saw that patients developed rash, fever, and arthralgia within 1 to 4 hours. The occurrence of these symptoms could be blocked by pretreatment with the IL-1 β inhibitor anakinra.¹²²

The subsequent fever attack varies in length, depending on the degree of cold exposure; generally it lasts a few hours to a maximum of 3 days. These episodes start at an early age, with 95% of patients having had their first fever episode in the first year of life—60% even within the first days of life. The symptoms tend to become less severe with advancing age.¹¹⁹ Type AA amyloidosis complicated by renal insufficiency has been described in at least three FCAS families.¹²¹

Muckle-Wells Syndrome

MWS (MIM 191900) is a rare autosomal dominant inflammatory disorder with incomplete penetrance. Patients have recurrent episodes of fever, abdominal pain, myalgia, urticarial rash (Figures 97-14 and 97-15), and conjunctivitis, frequently accompanied by arthralgia, arthritis with limb pain, or both. Attacks start in adolescence and can be provoked by hunger, fatigue, and sometimes exposure to cold.¹²³ The inflammatory episodes generally last 24 to 48 hours (see Figure 97-1) and start with ill-defined malaise and transient chills and rigor, followed by aching or lancinating pains in the distal limbs and larger joints. Arthralgia is a common feature of the attacks, but synovitis of the large joints is less common.¹²⁴ The rash consists of usually aching and sometimes pruritic erythematous papules 1 to 7 cm in diameter. In a few cases, genital and buccal aphthous ulcers have been seen.¹²⁵ Ocular symptoms include uveitis and conjunctivitis. Symptoms typically start in adolescence, although they have been reported at an earlier age. Late-onset development of perceptible deafness is common in MWS. Bone

Figure 97-14 Urticarial skin rash in a patient with Muckle-Wells syndrome. (Courtesy Dr. D. L. Kastner, National Institutes of Health, Bethesda, Md.)

Figure 97-15 Urticarial skin rash on the arm of a patient with Muckle-Wells syndrome. (Courtesy Dr. D. L. Kastner, National Institutes of Health, Bethesda, Md.)

involvement such as clubbing of nails and pes cavus can be seen as well. Most often, patients have a positive family history for the disease, which is indicative of autosomal dominant inheritance, but isolated cases have been reported. The most feared complication of the inflammatory attacks is type AA amyloidosis, which affects the kidneys first, leading to proteinuria and subsequent rapid progression to renal failure.

Chronic Infantile Neurologic Cutaneous and Articular Syndrome

CINCA or NOMID (MIM 607115) is a rare congenital disorder defined by the presence of the triad of (1) neonatal-onset skin lesions, (2) chronic aseptic meningitis, and (3) recurrent fever along with joint symptoms.¹²⁶ The key clinical feature of CINCA is a skin rash accompanied by peculiar joint manifestations and central nervous system involvement. The symptoms in CINCA begin right after birth or in the first months of life with a generalized skin rash. The disease follows an unpredictable course with persistent non-pruritic and migratory rash with fever, hepatosplenomegaly, and lymphadenopathy. Central nervous system involvement is not obvious from the outset, although some patients present with seizures, spasticity, or transient episodes of hemiplegia. In most patients, there are signs of chronic persistent aseptic meningitis.¹²⁷ Cerebrospinal fluid analysis may show mild pleocytosis, and there may be increased intracranial pressure. Brain imaging shows mild ventricular dilation, prominent sulci, central atrophy, and, in long-standing cases, calcifications of falces and dura.

In older children, headache is often a prominent feature as a sign of chronic meningitis. Mental retardation is present in almost all cases. Progressive sensorineural impairment leading to high-frequency hearing loss can be seen in a few cases. Ocular manifestations are prominent, with optic disc changes such as optic disc edema, pseudopapilledema, and optic atrophy, as well as anterior segment manifestations such as chronic anterior uveitis.¹²⁸ These symptoms may lead to visual impairment. Hoarseness, especially in older children, is typical. Joint and bone symptoms are a prominent feature of CINCA, and these manifest as bone inflammation, which gives rise to major arthropathies secondary

Figure 97-16 Severe deformational arthropathy of the knees in a patient with chronic infantile neurologic cutaneous and articular syndrome. (Courtesy Dr. A. M. Prieur, Hôpital Necker-Enfants Malades, Paris.)

to epiphyseal and metaphyseal disorganization. Growth cartilage alterations such as enlarged epiphyses and patellar overgrowth can be an impressive feature of the disease (Figures 97-16 and 97-17). Erosive changes occur, especially in the phalanges of hands and feet. There are typical dysmorphic features such as frontal bossing and a saddle nose. These common physical features are the reason CINCA patients give the impression that totally unrelated patients are siblings. The prognosis of these patients is grave; 20% die in childhood because of infections, vasculitis, and amyloidosis.¹²⁶

Diagnosis and Diagnostic Tests

Diagnosis starts with a thorough patient and family history (see Table 97-1). Hoffman and colleagues¹²¹ suggested a set

Figure 97-17 Radiograph of the knee in a patient with chronic infantile neurologic cutaneous and articular syndrome showing greatly enlarged epiphyses and patella with punctate increased density. (Courtesy Dr. A. M. Prieur, Hôpital Necker-Enfants Malades, Paris.)

Table 97-6 Diagnostic Criteria for Familial Cold Autoinflammatory Syndrome

1. Recurrent intermittent episodes of fever and rash that primarily follow generalized cold exposures
2. Autosomal dominant pattern of disease inheritance
3. Age of onset < 6 mo
4. Duration of most attacks <24 hr
5. Presence of conjunctivitis associated with attacks
6. Absence of deafness, periorbital edema, lymphadenopathy, and serositis

From Hoffman HM, Wanderer AA, Broide DH: Familial cold autoinflammatory syndrome: phenotype and genotype of an autosomal dominant periodic fever, *J Allergy Clin Immunol* 108:615–620, 2001.

of diagnostic criteria for FCAS after studying six large families with this syndrome (Table 97-6), but these have not been validated in an independent cohort. Laboratory examination during a fever episode in CAPS shows an acute-phase response with polymorphonuclear leukocytosis and increased erythrocyte sedimentation rate, but this does not differentiate among the periodic fever disorders. Symptoms such as an urticarial rash after cold exposure highly favor a diagnosis of FCAS. The ice cube test (i.e., holding an ice cube to a patch of skin to provoke urticaria), which is diagnostic in acquired cold urticaria, is negative in FCAS. Typical facial features such as frontal bossing and a long pediatric history including chronic aseptic meningitis point to CINCA/NOMID.

Genetic testing of the *CIAS1* gene can subsequently help to establish the genetic diagnosis. Usually, exon 3 of this gene is screened for mutations. There seems to be genetic heterogeneity in CINCA because not all patients have *CIAS1* mutations.

Treatment

Since the advent of IL-1 inhibition, it is the treatment of choice for patients with severe forms of cryopyrin-associated periodic syndrome.¹²⁹ Previously, high-dose oral corticosteroids were often used and found to be beneficial in some patients. NSAIDs, disease-modifying antirheumatic drugs, and cytotoxic drugs generally do not help.

IL-1 inhibition by anakinra was shown to be beneficial for patients with any of the cryopyrin-associated periodic syndromes in a number of case reports and case series.^{129,130} The largest study was by Goldbach-Mansky and colleagues,¹³⁰ who studied 18 patients with CINCA/NOMID, 12 of whom had mutations in the cryopyrin gene. All of them had a rapid and sustained response to daily subcutaneous injection of anakinra (1 to 2 mg/kg body weight), with decrease of symptoms, acute-phase response, and leptomeningeal lesions as seen on MRI. Mirault and colleagues¹³¹ described improvement of sensorineural deafness in a patient with MWS on treatment with anakinra.

Lachmann and colleagues published the results of a trial of the new IL-1 β antibody canakinumab in patients with CAPS,¹³² demonstrating the efficacy of an injection of 150 mg canakinumab once every 2 months. The first reports of the new IL-1 inhibitor IL-1-trap are also promising.¹²⁹

BLAU SYNDROME/EARLY-ONSET SARCROIDOSIS

Epidemiology

Blau syndrome,¹³³ also known as *familial granulomatous arthritis* (OMIM 186580), and early-onset sarcoidosis (OMIM 609464) (BS/EOS) are now recognized as the same disorder.^{134,135} “Pediatric granulomatous arthritis” has been suggested as a new name to describe this syndrome,¹³⁶ although this might, erroneously, give the impression that the disease occurs only in children. Little is known about its epidemiology, although it is thought to occur worldwide.¹³⁴

Etiology

The inheritance pattern of BS/EOS is autosomal dominant. In many cases, a *de novo* mutation is found, which explains the relatively high incidence of sporadic cases. These sporadic cases were often classified as early-onset sarcoidosis precisely because of the absence of affected relatives, but Blau syndrome and early-onset sarcoidosis have now been shown to be caused by mutations in the nucleotide-binding oligomerization domain 2/caspase recruitment domain 15 gene (*NOD2/CARD15*).^{135,137,138} Mutations are mostly located in exon 4 of *NOD2/CARD15*. The predominant mutations are two missense mutations at position 334 (R334Q and R334W)¹³⁶ (for details, see the online mutation database available at <http://fmf.igh.cnrs.fr/infevers/>).

Pathogenesis

The *NOD2/CARD15* protein is considered to be an intracellular sensor for pathogenic components, analogous to the Toll-like receptors. Activation of *NOD2/CARD15* results in a wide array of downstream effects that are still not well understood, including activation of NF κ B and mitogen-activated protein kinase pathways, turning on an innate immune response of diverse cytokines (e.g., IL-1 β) and defensins.¹³⁹

Seven of the nine different mutations of *NOD2/CARD15* linked to BS/EOS are located in the NOD domain of the protein, similar to the mutations in cryopyrin (NLRP3) in the cryopyrin-associated syndromes. The two most common mutations affect a codon at a homologous position in the NOD domain to the location of the cryopyrin R260W mutation.¹⁴⁰ This suggests a similar pathophysiologic effect on the function of the protein.

Polymorphisms in another part of this same *NOD2/CARD15* gene on chromosome 16 are associated with increased susceptibility to Crohn’s disease¹⁴¹; the risk of developing Crohn’s disease is increased 40-fold in individuals homozygous for these polymorphisms. Whether these polymorphisms result in a gain or loss of function of this protein is debated. There are some shared features between the two diseases: Both are characterized by granulomatous inflammation, and although bowel inflammation is not seen in Blau syndrome, Crohn’s disease can manifest with uveitis, arthritis, and skin rash.

Clinical Features and Outcome

The clinical phenotype of BS/EOS consists of recurrent granulomatous inflammations. The three typical sites affected are joints, eyes, and skin. The granulomatous arthritis is most often polyarticular, with a synovitis or tenosynovitis.¹³⁴ The uveitis associated with this disorder tends to follow a chronic, persistent course. It can be an acute anterior uveitis, but it often extends to a panuveitis.¹³⁶ Cataracts, secondary glaucoma, and significant visual impairment can result. Involvement of the skin results in a papular, erythematous skin rash with associated dermal granulomas, usually generalized and intermittent, on trunk and extremities.¹⁴² Other symptoms include campyloactyly (contracture of multiple interphalangeal joints), cranial neuropathies, fever, and arteritis.¹³⁷ In some severely affected patients, granulomatous inflammation can disseminate at an advanced stage into a systemic disease, with granulomas in liver, lung, and kidney.¹³⁶ Onset is generally before age 5. In familial cases, genetic anticipation is often observed (i.e., the course of disease tends to be more severe in later generations). The major long-term complications are joint deformity and visual impairment.¹³⁴

Diagnosis

The most important aspect of diagnosis is the histologic evidence of granulomas at the site of inflammation. This evidence can be obtained by biopsy of any involved site, of which skin is least invasive. One study showed that skin biopsy was diagnostic in all cases with the typical skin rash, whereas synovial biopsy was not positive in all patients, perhaps owing to sampling error.¹³⁶ Genetic testing is available for *NOD2/CARD15* mutations, but in some series, not all patients with a typical clinical phenotype carried a mutation in this gene.¹³⁷

Treatment

There are no controlled studies of management of BS/EOS patients. There tends to be a poor response to NSAIDs. A good response to the TNF inhibitor infliximab was reported in case reports,^{143,144} one of which also noted that etanercept did not have the same effect. IL-1 blockade by anakinra was also reported as beneficial in a case description,¹⁴⁵ although in two other cases anakinra was not effective.¹⁴⁶ Thalidomide was effective in two children in Japan.¹⁴⁷ The panuveitis is usually managed by topical, subconjunctival, or systemic corticosteroids.¹³⁴

PYOGENIC STERILE ARTHRITIS, PYODERMA GANGRENUM, AND ACNE SYNDROME

Epidemiology

Pyogenic sterile arthritis, pyoderma gangrenosum, and acne (PAPA) syndrome (MIM 604416) is an autosomal dominant disorder first described by Lindor and colleagues.¹⁴⁸ Fewer than 20 families have been reported.

Etiology/Pathogenesis

Wise and colleagues¹⁴⁹ identified mutations in the CD2-binding protein 1 (*CD2BP1*) gene as the cause of PAPA syndrome. *CD2BP1*, also known as *proline-serine-threonine phosphatase interacting protein 1* (PSTPIP1), is highly expressed in neutrophils¹¹² (see the online mutation database available at <http://fmf.igh.cnrs.fr/infevers/>).

PSTPIP1 can form interactions with pyrin, the protein mutated in FMF.¹⁵⁰ The mutations in PAPA syndrome result in hyperphosphorylation of PSTPIP1,¹⁵⁰⁻¹⁵² which increases the strength of the interaction between PSTPIP1 and pyrin. This increased interaction of PSTPIP1 and pyrin leads to increased IL-1 β production. This activity correlated with a higher IL-1 β production in response to lipopolysaccharide stimulation of peripheral blood leukocytes from a PAPA patient ex vivo compared with a healthy control.¹⁵⁰ It places PAPA syndrome in the same pathogenic pathway as FMF. Other studies report an increased production of TNF.^{153,154} Dysregulated apoptosis may also be involved.¹⁵⁵

Clinical Features and Outcome

The episodic inflammation in this syndrome includes, as the name aptly indicates, symptoms of pyogenic sterile arthritis, pyoderma gangrenosum, and severe cystic acne. Lesions generally occur at the site of mild physical trauma, but sometimes no obvious trigger can be discerned.¹⁴⁸ The inflammation can be severe and eventually may lead to destruction of joints, muscle, and skin. Fever is not prominent in this syndrome. Onset is usually from age 1 to 16 years.^{148,156} The acne generally starts early in puberty and persists in adulthood.

Diagnosis

No specific diagnostic test exists. Diagnosis is based on a finding of the typical constellation of symptoms and a positive family history. A specialized DNA diagnostics department would be able to perform the genetic test for PAPA syndrome. At this time, it is unknown whether this genetic test would detect all patients or whether other genes could be involved.

Treatment

Diverse anecdotal evidence is only available on treatment options in PAPA syndrome. High-dose steroids generally have a positive effect on the pyoderma gangrenosum but may be associated with increased acne.¹⁴⁸ Pyogenic arthritis is often responsive to glucocorticoids intra-articularly and orally.¹⁵⁶ Varying results have been reported with anti-cytokine treatment. The TNF inhibitor etanercept was reported to be beneficial,^{153,157} as was the IL-1 inhibitor anakinra.^{150,158,159} Stichweh and colleagues¹⁶⁰ reported on a patient with severe pyoderma gangrenosum, however, who did not respond to either etanercept or anakinra, but in whom the other TNF inhibitor infliximab did prove successful.

DEFICIENCY OF THE IL-1 RECEPTOR ANTAGONIST

Deficiency of the IL-1 receptor antagonist (DIRA) is the latest discovery of a monogenetic disorder in the group of autoinflammatory diseases.^{161,162} It was found in nine patients from six families, one from Newfoundland, Canada, three from the Netherlands, one from Puerto Rico, and one consanguineous family from Lebanon.

All patients were homozygous for mutations affecting the gene encoding the IL-1 receptor antagonist (IL-1ra), designated *IL1RN*.¹⁶¹ These mutations resulted in an absence of secretion of IL-1ra. IL-1ra is an endogenous inhibitor of the inflammatory cytokines IL-1 α and IL-1 β . The patients showed signs of unopposed IL-1 signaling leading to overproduction of other inflammatory cytokines and chemokines.

The clinical phenotype is present at birth or in the first month of life. Features include primarily cutaneous pustulosis and sterile pustulous osteomyelitis. Patients do not present with fever. Two children died of multiorgan failure secondary to severe inflammatory response syndrome (SIRS) at the ages of 2 months and 21 months, and a third child died at 9.5 years of complications of pulmonary hemosiderosis with progressive intestinal fibrosis.

The diagnosis is made by a combination of the clinical features and an impressive response to anakinra. Anakinra is a synthetic version of IL-1ra and thus supplements the missing protein in DIRA. Treatment with anakinra suppresses all disease symptoms, although in one patient inflammatory markers remained elevated.

CONCLUSION

The familial autoinflammatory syndromes are characterized by recurrent episodes of fever and inflammation. This group of disorders should be considered in a patient with a history of years of such inflammatory attacks with symptom-free intervals in between (except for CINCA/NOMID, in which some symptoms and morphologic features persist). Dysregulation of the IL-1 β pathway is central to many familial autoinflammatory syndromes, especially CAPS, FMF, and DIRA. Increasing availability of IL-1 inhibitors has revolutionized treatment options in many of these diseases.

The discovery of the causative genes has had an enormous impact in the field of periodic fevers. This discovery has been made possible because of the accurate phenotypic characterization of patients with periodic fever. Careful analysis and proper clustering of these patients is indispensable to allow the elucidation of the genetic background and the evaluation of possible treatment options (Table 97-7). Central periodic fever registries have afforded the opportunity to appreciate previously unrecognized symptoms, to give insight into the long-term prognosis, and to allow better evaluation of drug regimens. Despite these efforts at classification, however, many patients with periodic fever do not fall in one of the previously mentioned disease categories. It is to be expected that in the future other periodic fever syndromes and corresponding genes will be discovered.

Table 97-7 Summary of Treatment Options

Disorder	Treatment Options
FMF	Colchicine In refractory cases or intolerance of colchicine: intravenous colchicine; IL-1 inhibition (anakinra)
HIDS	Simvastatin; etanercept; IL-1 inhibition (anakinra)
TRAPS	NSAIDs; etanercept; IL-1 inhibition (anakinra)
CAPS	IL-1 inhibition (anakinra, canakinumab, IL-1 trap)
BS/EOS	Corticosteroids; infliximab?
PAPA	High-dose steroids; IL-1 inhibition (anakinra); etanercept; infliximab

BS/EOS, Blau syndrome/early-onset sarcoidosis; CAPS, cryopyrin-associated periodic syndrome; FMF, familial Mediterranean fever; HIDS, hyper-IgD syndrome; IL-1, interleukin-1; NSAIDs, nonsteroidal anti-inflammatory drugs; PAPA, pyogenic sterile arthritis, pyoderma gangrenosum, and acne; TRAPS, tumor necrosis factor receptor-associated periodic syndrome.

Pathogenesis of Osteoarthritis

PAUL E. DI CESARE •
DOMINIK R. HAUDENSCHILD •
JONATHAN SAMUELS •
STEVEN B. ABRAMSON

KEY POINTS

Osteoarthritis is a degenerative joint disease, occurring primarily in older individuals, characterized by erosion of the articular cartilage, hypertrophy of bone at the margins (i.e., osteophytes), subchondral sclerosis, and a range of biochemical and morphologic alterations of the synovial membrane and joint capsule.

Risk factors for developing osteoarthritis include age, joint location, obesity, genetic predisposition, joint malalignment, trauma, and gender.

Morphologic changes in early osteoarthritis include articular cartilage surface irregularity, superficial clefts within the tissue, and altered proteoglycan distribution.

Morphologic changes in late osteoarthritis include deepened clefts, increase in surface irregularities, and eventual articular cartilage ulceration, exposing the underlying bone. Chondrocytes form clusters or clones in an attempt at self-repair. In addition, marginal osteophytes can form.

The matrix metalloproteinase family of proteinases degrades proteoglycans (aggrecanases) and collagen (collagenases).

A suboptimal repair response of normal articular cartilage to injury typically results in secondary osteoarthritis.

Chondrocytes sense and respond to mechanical and physicochemical stimuli via several regulatory pathways.

Mediators classically associated with inflammation during the course of osteoarthritis include interleukin-1 β and tumor necrosis factor.

Nitric oxide, produced by the inducible isoform of nitric oxide synthase, is a major catabolic factor produced by chondrocytes in response to proinflammatory cytokines.

Expression of inducible cyclooxygenase-2 is increased in osteoarthritis chondrocytes.

Low-grade inflammation occurs in osteoarthritic synovial tissues and contribute to disease pathogenesis.

Most current treatments aim to improve the signs and symptoms of osteoarthritis.

Osteoarthritis (OA) is a degenerative joint disease, occurring primarily in older persons, characterized by erosion of the articular cartilage, hypertrophy of bone at the margins (i.e., osteophytes), subchondral sclerosis, and a range of biochemical and morphologic alterations of the synovial membrane and joint capsule. Pathologic changes in the late stages of OA include softening, ulceration, and focal disintegration of the articular cartilage; synovial inflammation may also occur. Typical clinical symptoms are pain and stiffness, particularly after prolonged activity.

In industrialized societies OA is the leading cause of physical disability, increases in health care usage, and impaired quality of life. The impact of arthritic conditions is expected to grow as the population both increases and ages in the coming decades.¹ Despite its prevalence, the precise etiology, pathogenesis, and progression of OA remain beyond our understanding, primarily due to multiple confounding factors. Without a clear-cut picture of how OA arises at the cellular or molecular level, many still consider it a result of “wear and tear,” an inevitable consequence of aging. In fact, the accompanying biochemical, structural, and metabolic changes in joint cartilage have been well documented. It is now known, for example, that cytokines, mechanical trauma, and altered genetics are involved in its pathogenesis and that these factors can initiate a degradative cascade that results in many of the characteristic alterations of articular cartilage in OA. More recently it has become apparent that OA is a disease process that affects the entire joint structure including cartilage, synovial membrane, subchondral bone, ligaments, and periarticular muscles. OA is thus better considered a group of overlapping disorders of various etiologies arising from a combination of systemic factors (e.g., genetics) and local factors (e.g., biomechanically or biochemically mediated events) that gradually converge to produce a condition with definable morphologic and clinical outcomes.²

OA may be classified as primary or secondary according to its cause or major predisposing factor; what they all have in common is altered cartilage physiology. Primary OA is the most common type and has no identifiable etiology or predisposing cause. Secondary OA, although it has an identifiable underlying cause, is pathologically indistinguishable

from primary OA. The most common causes of secondary OA are metabolic conditions (e.g., calcium crystal deposition, hemochromatosis, acromegaly); anatomic factors (e.g., leg length inequality, congenital hip dislocation); traumatic events (e.g., major joint trauma, chronic joint injury, joint surgery); or the sequelae of inflammatory disorders (e.g., ankylosing spondylitis, septic arthritis). In the case of secondary OA arising from inflammatory joint disease, cartilage degeneration most likely results initially from degradative enzymes released from the synovium or leukocytes within the joint space and later from the mechanical attrition of a biomechanically altered extracellular matrix. Distinguishing between primary and secondary OA may be difficult because the clinical presentation and symptoms are often so similar.

ETIOLOGIC FACTORS IN OSTEOARTHRITIS

Major factors affecting degree of risk for developing OA include age, joint location, obesity, genetic predisposition, joint malalignment, trauma, and gender.

Age

Age is the risk factor most strongly correlated with OA.^{3,4} OA is the most common chronic disease in later life; more than 80% of persons older than age 75 years are affected, and OA increases progressively with age at all joint sites. Radiologic changes in OA increase as individuals age,⁵ although these changes do not always correlate with clinical symptoms or disability.^{6,7} Although clearly an age-related disease, OA is not, however, an inevitable consequence of aging. Age-related morphologic and structural changes in articular cartilage include fraying, softening, and thinning of the articular surface; decreased size and aggregation of matrix proteoglycans; and loss of matrix tensile strength and stiffness. These age-related tissue changes are most likely due to a decrease in the chondrocytes' ability to maintain and repair the tissue, as chondrocytes themselves undergo age-related decreases in mitotic and synthetic activity, exhibit decreased responsiveness to anabolic growth factors, and synthesize smaller and less uniform large aggregating proteoglycans and fewer functional link proteins.⁴

There also appears to be a direct correlation between chondrocyte apoptosis and cartilage degradation leading to OA. Age does appear to be an independent factor that predisposes articular chondrocytes to apoptosis because the expression levels of specific proapoptotic genes (Fas, FasL, caspase-8, and p53) is higher in aged cartilage.^{8,9}

Joint Location

Although osteoarthritis occurs most commonly in weight-bearing joints,¹⁰ age affects joints differentially.¹¹ A study comparing tensile fracture stress of cartilage in the femoral head and in the talus showed that it decreased progressively with age in the former but not in the latter.¹² Joint-specific age-related viability in articular cartilage may explain why OA is more common in hip and knee joints with increasing age but occurs rarely in the ankle.

Obesity

Obesity is another important risk factor for OA.¹³⁻¹⁵ Greater body mass index in both women and men has been shown to be associated with an increased risk of knee (but not hip) OA.^{7,16,17} An increase in mechanical forces across weight-bearing joints is probably the primary factor leading to joint degeneration. Obesity not only increases the forces at weight-bearing joints but may also change posture, gait, and physical activity level, any or all of which may further contribute to altered joint biomechanics.¹⁸ The majority of obese patients exhibit varus knee deformities, which results in increased joint reactive forces in the medial compartment of the knee, thereby accelerating the degenerative process.¹⁹

Particularly in elderly obese individuals, heavy physical activity is an additional risk factor for the development of knee OA, whereas light to moderate activity does not appear to increase risk for knee OA and may in fact alleviate symptomatic knee OA by reducing body mass index.^{7,16,17} Similarly, weight loss can reduce both radiographic knee OA progression and clinical symptoms. Recent evidence indicates that in obese patients with OA, significant weight loss dramatically improves functional status, with short-term results equivalent to those of patients who have undergone joint replacement.²⁰

Yet recent work suggests that the association between obesity and osteoarthritis lies beyond the mechanical loading from a higher body mass index. Adipose tissue is now recognized as a metabolically active contributor to inflammatory cascades. Activated adipose tissue increases the synthesis of proinflammatory cytokines including leptin, adiponectin, resistin, interleukin-1 (IL-1), IL-6, and tumor necrosis factor (TNF), while some regulatory cytokine levels such as IL-10 are decreased.^{21,22} Specifically, the discovery of the obesity gene and its product leptin may have important implications for the onset and progression of OA and increase our understanding of the link between obesity and OA. The fact that women have a greater proportion of total body fat and relatively higher levels of adipose-derived systemic leptin concentrations than men may partially account for the gender disparity in OA patients. Leptin, however, is produced not only by adipose cells but also by osteoblasts and chondrocytes, suggesting that local leptin production may play a role in OA. Significant levels of leptin were observed in the cartilage and osteophytes of subjects with OA, yet few chondrocytes produced leptin in the cartilage of healthy subjects. Leptin has also been demonstrated to induce anabolic activity in the chondrocytes of rats and thus may ultimately confer structural joint changes.^{23,24}

Genetic Predisposition

Because of the prevalence of OA in the general population and its extensive clinical heterogeneity, the genetic contribution to its pathogenesis has been difficult to analyze.^{25,26} Two major cohorts (the Framingham Study and the Baltimore Longitudinal Study on Aging) support a genetic contribution to OA, with evidence for a major recessive gene and a multifactorial component, representing either polygenic or environmental factors.^{27,28} Twin pair and family risk

studies have indicated that the heritable component of OA may be on the order of 50% to 65%.^{26,29,30} Moreover, family, twin, and population studies have indicated differences among genetic influences that determine the site of OA (hip, spinal, knee, hand).^{28,31,32} Further evidence supporting a genetic predisposition to OA is the demonstration of a significantly higher concordance for OA between monozygotic twins than between dizygotic twins. Genetic studies have identified multiple gene variations associated with an increased risk of OA.³³

Inherited forms of OA may be caused by mutations in several genes that are expressed in cartilage including those encoding types II, IV, V, and VI collagens, as well as cartilage oligomeric matrix protein (COMP).^{34,35} Recently it was reported that mice deficient in the type IX collagen gene and the matrilin 3 gene (human equivalent condition not yet reported) developed age-dependent OA-like changes in the knee and temporal mandibular joints.^{36,37} Moreover, candidate genes in OA have been identified that are not structural proteins. The haplotype of a vitamin D receptor (VDR) that plays a vital role in controlling bone mineral density appears to be associated with a twofold risk of knee OA³⁸⁻⁴⁰—although the VDR locus is close to the COL2A1 locus on chromosome 12q, so the association may be due to linkage disequilibrium with the latter.²⁵ In addition, the locus of the insulin-like growth factor 1 (IGF-1) gene has been associated with radiographic OA, as has an aggrecan polymorphic allele with hand OA.²⁵

In population studies, genome-wide linkage scans have highlighted up to seven chromosomal regions that may harbor OA susceptibility genes.⁴¹ Chromosome 2q was positive in several scans, suggesting that this chromosome is likely to harbor one or more susceptibility genes. In a study of affected sibling pairs, a region of linkage stretching from 2q12 to 2q21 was reported for OA of the distal interphalangeal joint and a previous study of affected sibling pairs in the United Kingdom demonstrated a broader region of linkage, stretching from 2q12 to 2q31.^{41,42} Two IL-1 genes (*IL1A* and *IL1B*) and the gene encoding IL-1Ra (*IL1RN*) are located on chromosome 2q13 within a 430-kb genomic fragment. Given the importance of IL-1 in the perpetuation of cartilage damage in OA, it is possible that a proportion of the genetic susceptibility to OA may be encoded for by variation in the activity of interleukins, and that for chromosome 2q this susceptibility could reside within the IL-1 gene clusters. Loughlin and colleagues,⁴¹ however, have provided evidence that the IL-1 gene cluster harbors susceptibility for knee OA, but not for hip OA. These and other epidemiologic studies have highlighted potential differences in the degree of OA heritability among different joint groups and between the two sexes.^{43,44}

Genomic and postgenomic technology, in addition to defining susceptibility genotypes, will also lead to the discovery of genes and gene products that are overexpressed in OA tissues and that contribute to disease pathogenesis and progression.⁴⁵⁻⁴⁷ Studies of differential gene expression in diseased tissue, in addition to elucidating pathogenic processes that lead to novel therapies, could also have two additional benefits: (1) identification of unique biomarkers that can be used for OA diagnosis or management and (2) identification of candidate susceptibility genotypes such as

polymorphic variations of cytokines or growth factors that may predispose to disease progression.⁴⁸

Joint Malalignment and Trauma

Joint malalignment or trauma may lead to rapid development of OA, or it may initiate a slow process that results in symptomatic OA years later. Probably as a result of progressive reduction in periarticular blood flow and the resultant decrease in rate of remodeling at the osteochondral junction, joints become increasingly congruent with age.^{49,50} Altered joint geometry may interfere with nutrition of the cartilage, or it may alter load distribution, either or which may result in altered biochemical composition of the cartilage, irrespective of age.^{51,52} Local factors such as stresses related to joint use and joint deformity also influence the development of OA.

Joint incongruence (e.g., malreduced intra-articular fractures, developmental dysplasia of the hip, recurrent dislocation of the patella) can lead to early-onset OA.⁵³ Repetitive, high-impact sports are strongly associated with joint injury and increase the risk for lower limb OA.⁵⁴ Repetitive trauma at a subfracture level has been shown to accelerate remodeling in the zone of calcified cartilage, with reduplication of the tidemark and thinning of the noncalcified zone, resulting in stiffening of the subchondral bone, increased wear of the overlying cartilage, and ultimately development of OA.⁵⁵⁻⁵⁷ Regular exercise is important in maintaining articular cartilage structure and metabolic function. Recreational running and low-impact activities have not been shown to increase the risk of OA.

Articular cartilage is remarkably resistant to damage by shear forces; it is, however, highly vulnerable to repetitive impact loading.⁵⁸ When joints are subjected to in vitro cyclic loads that are easily borne by subchondral bone, cartilage degeneration still results.⁵⁹ This vulnerability accounts for the high frequency of OA in shoulders and elbows of pneumatic drill operators and baseball pitchers, ankles of ballet dancers, metacarpophalangeal joints of boxers, and knees of basketball players. The risk for knee osteoarthritis among participants in sports, however, may be more closely related to previous knee injury than to participation in sport alone.⁶⁰

The major forces on articular cartilage, in addition to weight bearing, are due to the contraction of the muscles that stabilize or move the joint.⁶¹ For example, in normal walking, 4 to 5 times the body weight may be transmitted through the knee, and in squatting it is up to 10 times the body weight.³⁹ Articular cartilage is believed to be too thin to be an effective shock absorber under these high loads. What protects the joint under physiologic conditions of impact loading is joint motion, with the associated lengthening of muscles under tension and deformation of the subchondral bone.^{40,62} Cancellous subchondral bone functions as a major shock absorber due to its material properties.⁵⁶ Two-thirds of subchondral bone stiffness derives from bony trabeculae, about one-third from intraosseous fluid.⁶³ In the normal unloaded joint, the opposing surfaces are not congruous; under loading, both the cartilage and the bone deform so that a larger proportion of the opposing surfaces comes into contact, increasing joint congruity and resulting in a force distribution over the largest possible area.⁶⁴

Excessive loads may cause microfractures of subchondral trabeculae that heal via callus formation and remodeling, resulting in stiffer-than-normal bone that is less effective as a shock absorber and predisposing articular cartilage to degeneration.

Whether subchondral sclerosis precedes the onset of OA or is a change secondary to cartilage degeneration is not known. Indirect evidence supports the theory that biomechanical changes in subchondral bone may be important in OA.^{63,65,66} Foss, for example, reported cases of femoral osteoporosis (which is associated with softening and greater compliance of the subchondral bone) that may have protected the hip from OA.⁶⁷ Conversely, *in vitro* studies have shown that stiffening of the cancellous bone with methacrylate, reducing its deformability, leads to cartilage degeneration with repetitive impact loading.⁶⁸

Gender

Women are about twice as likely as men to develop OA. Although women have a lower prevalence of OA than men before age 50 years, there is a marked increase in prevalence among women after 50, particularly in the knee.⁶⁹ Radiographic and interview data from the National Health and Nutrition Examination Survey (NHANES III), a representative cross-sectional health examination survey of the U.S. population, reported that the lifetime prevalence of radiographic knee osteoarthritis was 37.4% and that the prevalence of symptomatic knee osteoarthritis was 12.1% in adults age 60 years and older; prevalence was greater among women than men (42.1% vs. 31.2%), and women had significantly more Kellgren-Lawrence grade 3 and 4 changes (12.9% vs. 6.5% in men).⁷⁰ Women have a greater number of joints involved and are more likely to exhibit clinical symptoms of morning stiffness, joint swelling, and nocturnal pain. The gender differences in OA incidence after age 50 may be the result of postmenopausal estrogen deficiency. Articular chondrocytes possess functional estrogen receptors, suggesting that these cells can be regulated by estrogen. Nuclear estrogen receptors (ERs) have been detected in articular chondrocytes of humans,^{71,72} rats,^{72,73} monkeys,^{72,74} pigs,⁷⁵ and human growth plate chondrocytes.⁷⁶

Recent epidemiologic studies have linked estrogen replacement therapy (ERT) with a lower-than-expected risk of knee and hip OA in postmenopausal women. Clinical investigations of the association between OA and hormonal level in women have involved measurement of circulating estrogen levels in postmenopausal women, general radiographic evaluation of postmenopausal women, and examination of the effect of ERT on such variables as knee OA and cartilage volume.⁷⁷⁻⁸⁰ In a study of more than 4000 women age 65 years or older that assessed pelvis radiographs for hip OA, Nevitt and colleagues⁷⁷ showed that women using oral estrogen faced a significantly reduced risk of hip OA. Estrogen users for 10 years or longer had a greater reduction in risk of developing hip OA than users for less than 10 years. Zhang and colleagues,⁷⁹ using weight-bearing radiographs in female participants in the Framingham Osteoarthritis Study ($n = 831$; mean age, 73 years; age range, 63 to 93) to study the rate of knee OA, reported a modest but nonsignificant greater protective effect for

radiographically detected OA in women who were on ERT. A prospective cohort study using anteroposterior weight-bearing knee radiographs of women (mean age, 71 years; age range, 63 to 91) from the Framingham Study categorized patients into three groups according to estrogen use at biennial examination: never users ($n = 349$), past users ($n = 162$), and current users ($n = 40$). When both incident and progressive radiographic knee OA cases were combined, current ERT users were found to have 60% less risk for knee OA than never users. Wluka and colleagues⁸⁰ reported on the longer-term use of ERT and its association with knee cartilage volume (measured by magnetic resonance imaging [MRI]) in postmenopausal women; results showed that after adjusting for confounders, women using long-term ERT had more knee cartilage than controls. Beneficial effects of ERT on the severity of knee OA in ovariectomized monkeys have also been demonstrated.⁸¹

CHANGES IN OSTEOARTHRITIS

Morphologic Changes

In early OA, the articular cartilage surface becomes roughened and irregular, and superficial clefts within the tissue become apparent. Histologically, the surface is fibrillated and small cracks are apparent but limited to the upper layers of the surface zone. These changes show evidence of mechanical wear and are often accompanied by matrix swelling and chondrocyte proliferation or, to a limited extent, apoptosis near the articular surface. Proteoglycan distribution is altered, as revealed by histochemical staining. As OA progresses, the articular cartilage surface becomes more irregular and the superficial clefts within the tissue become enlarged and extend beyond the superficial zone and into the middle zone of cartilage. The previously isolated and focal portions of damaged cartilage become increasingly contiguous. Portions of the superficial zone are completely missing in focal lesions. As the condition worsens, the clefts deepen, surface irregularities increase, and the articular cartilage eventually ulcerates, exposing the underlying bone. As the disease continues to progress, the joint articulates on exposed bone, causing eburnation and thickening of the bone. The eburnated bone becomes denser and more metabolically active in response.

Early Reparative, Proliferative, and Hypertrophic Changes

Attempts at local self-repair can be seen as an initial increase in the number of chondrocytes in the form of clusters or clones, with as many as 50 or more cells in a cluster³⁹ (Figure 98-1). In healthy cartilage, chondrocytes are quiescent and neither commit to proliferation nor to further hypertrophic differentiation. In contrast, in the early stages of OA, proliferating chondrocytes in clusters express higher levels of matrix proteins including aggrecan and type II collagen,⁸³ as well as stem cell markers⁸⁴ and markers of hypertrophic differentiation.⁸³ The chondrocyte clusters with proliferative and hypertrophic markers are a hallmark of OA and are also prominent in animal models of OA and three-dimensional cell cultures.⁸⁵ In addition to being a repair response, chondrocyte clusters are thought to contribute to

Figure 98-1 Histologic sections of normal (*left*) and osteoarthritic (*right*) articular cartilage obtained from the femoral head. The osteoarthritic cartilage has surface irregularities, with clefts to the radial zone and cloning of chondrocytes.

OA pathogenesis and progression through the release of matrix-degrading enzymes, growth factors, and inflammatory cytokines that affect surrounding chondrocytes and joint tissues.⁸⁵

Osteophyte Formation

Osteophytes consist of newly formed fibrocartilage and bone and are most commonly formed at the peripheral margins of joints at the interface between cartilage and the periosteum. Osteophytes are thought to arise through chondrogenic differentiation of progenitor cells, most commonly from within the periosteum.⁸⁶ As such, osteophytes may be a cellular repair response to the altered growth factor environment after joint injury, and in certain cases osteophytes can contribute to the stability of the joints.^{87,88} The connection between osteophyte formation and the repair response is further strengthened by animal models of OA in which the early stages of osteophyte formation can be histologically apparent as early as 3 days after joint injury. Many growth factors that enhance *in vitro* chondrogenic differentiation of stem cells are also present in osteophytes, including members of the transforming growth factor (TGF)- β superfamily,⁸⁹ bone morphogenetic proteins (BMPs),⁹⁰ IGF, and fibroblast growth factor,⁸⁶ and TGF- β can induce osteophyte formation in animal models.⁹¹ As OA progresses, the osteophytes can limit movement and become painful.

Hypocellularity

A reduction in cell number is observed in aging cartilage, and the reduced synthetic capability of hypocellular cartilage is a contributing factor to the initiation and progression of OA. In healthy adult femoral cartilage, the cell density varies between 24,000/mm³ in the surface zone and 8000/mm³ in the deep zone, with an average of 1.65% of the cartilage volume consisting of cells.⁹² This number is greatly reduced in OA, through cell death via necrosis or apoptosis.⁹³ Necrosis can result from direct mechanical damage to cells and is not generally an active process, whereas apoptosis is an active energy-consuming process. Apoptotic chondrocyte death can be initiated by many factors that are involved in the initiation and progression of arthritis

including mechanical damage or injury, changes in cell-matrix interactions, oxidative stress resulting from nitric oxide or other reactive oxygen species, impaired mitochondrial function, and signal transduction pathways such as CD95/CD95 ligand. These pathways ultimately converge, and the execution of apoptotic cell death is mediated by the activation of caspases. Inhibition of apoptosis by interfering with caspase activation following injury is being explored as a chondroprotective intervention to prevent secondary OA following injury. Compromised regulation of cellular senescence and autophagy can also cause cell death. The role of autophagy in inflammation and pathogenesis has been gaining the attention of researchers.⁹⁴ In some circumstances cell death can be mediated by the autophagic degradation of the damaged organelles. In cartilage, autophagy can be protective, and its reduction in OA corresponds with increased apoptotic markers.⁹⁵

ALTERATIONS IN CARTILAGE MATRIX METABOLISM

Biochemical Changes

These morphologic changes are accompanied by changes in the biochemical composition of the cartilage, which vary from early to later stages in the disease process. In early OA, the water content of the articular cartilage significantly increases, causing the tissue to swell and altering its biomechanical properties. This phenomenon suggests that there has been weakening of the collagen network; the type II collagen fibers have a smaller diameter than normal cartilage, and the normally tight weave in the midzone is slackened and distorted.⁹⁶⁻¹⁰¹

In later stages of OA, type I collagen concentration within the extracellular matrix increases and the proteoglycan concentration falls to 50% or less than normal, with less aggregation and shorter glycosaminoglycan side chains.^{98,102} Keratan sulfate concentration decreases, and the ratio of chondroitin-4-sulfate to chondroitin-6-sulfate increases, reflecting synthesis by chondrocytes of a proteoglycan profile more typical of immature cartilage.¹⁰³ Proteoglycan concentration in the cartilage diminishes progressively

until the end stages, when histologic staining detects little or none.¹⁰⁴

Our understanding of how the biochemical changes progress from the early to the later stages of OA is evolving. One of the first steps in cartilage degradation is a decrease in the density of proteoglycans. This step is thought to be at least partly reversible.¹⁰⁵ However, decreased proteoglycan density opens up the cartilage porosity to make it more permeable to collagenases and other proteases, and it exposes collagen fibrils. This initiates a vicious circle of positive-feedback loops that further promote cartilage degradation. For example, epitopes on collagen become accessible to the DDR2 receptor on the cell surface, which then increases MMP-13 production through activation of the Ras/Raf/MEK/ERK and p38 signal cascades.¹⁰⁶ The partially digested matrix components themselves have cytokine-like activity that enhances the inflammatory response and promotes matrix degradation. The destruction of the collagenous cartilage component is thought to be irreversible.

Calcium crystals (e.g., calcium pyrophosphate dihydrate, basic calcium phosphate crystals) are commonly found in the cartilage of the elderly, and often crystal arthropathy coexists with OA.¹⁰⁷ That calcium crystals play a role in causing or worsening OA is supported by clinical and laboratory studies, but the relationship is complex and it is unclear whether these crystals are directly involved in OA pathogenesis.¹⁰⁸⁻¹¹⁰ Pyrophosphate (PP) is produced from adenosine triphosphate (ATP) by the exoenzyme nucleoside pyrophosphohydrolase.¹¹¹ High levels of PP in synovial fluid from OA patients correlate directly with the severity of joint damage.^{112,113} Young or proliferating chondrocytes are a major source of PP, whereas resting chondrocytes from normal adult cartilage secrete little.¹¹¹ Thus the increased PP secretion in OA cartilage might indicate increased chondrocyte metabolic activity toward matrix repair.¹¹⁴ The presence of CPPD may alter the biomechanical properties of the cartilage extracellular matrix and lead to cartilage breakdown. Hemochromatosis (hemosiderin), Wilson's disease (copper), ochronotic arthropathy (homogentisic acid polymers), gouty arthritis (crystals of monosodium urate), and calcium pyrophosphate dihydrate (CPPD) crystal deposition disease are further examples of conditions in which the abnormal entity may alter the cartilage extracellular matrix, leading to either direct or indirect chondrocyte injury by increasing the stiffness of the tissue and thereby precipitating the development of OA.

Metabolic Changes

Early OA is characterized by increased synthesis of proteoglycans, collagen, noncollagenous proteins, hyaluronate, and cell replication.^{104,115} This "activation" of chondrocytes is thought to be an attempt to repair the cartilage matrix, although it is not always effective and yields a matrix of inferior quality that is more susceptible to degradation.¹¹⁶ However, both anabolic and catabolic processes increase as cells attempt to repair or maintain tissue integrity⁹⁸ and it is the imbalance between synthesis and degradation that is important in the pathogenesis of OA.¹¹⁷ In later stages of OA, there is a decrease in the synthesis of matrix

per cell and a decrease in cell number. Furthermore, the quality of the synthesized matrix is reduced with respect to the composition and distribution of their glycosaminoglycans, the size of the proteoglycan subunit, and their ability to aggregate with hyaluronic acid.^{98,100,103,118,119} In addition to the reduced matrix production and hypocellularity, there is increased synthesis and activation of matrix degrading enzymes, as well as an overall decrease in the concentrations of enzyme inhibitors such as tissue inhibitors of metalloproteinases (TIMPs). Eventually OA progresses when the chondrocytic anabolic repair processes cannot keep pace with catabolic processes.^{98,104} The complex interaction between matrix synthesis and degradation explains why OA typically is slowly progressive and at times remains static by morphologic criteria, but ultimately it results in the overall degradation of cartilage matrix. The following sections summarize the major anabolic and catabolic factors relevant to cartilage degradation and the pathogenesis of OA.

Anabolic Factors (Transforming Growth Factor- β , Bone Morphogenetic Proteins) and Cartilage Repair

TGF- β is essential for the formation and maintenance of cartilage (reviewed in Reference 120). Interference with TGF- β function in cartilage leads to OA in multiple animal models¹²¹ and in human genetic susceptibility to OA.¹²² TGF- β affects cartilage homeostasis at multiple levels: It enhances stem cell chondrogenesis to increase the pool of cells available for cartilage synthesis, and it increases matrix production in existing chondrocytes. TGF- β also increases synthesis of anticatabolic factors such as TIMPs and PAI-1, proteins that inhibit the activation of latent proteinases in cartilage. TGF- β attenuates the cellular response to inflammatory cytokines including IL-1 β and TNF,¹²⁰ and TGF- β signaling through the Smad2/3 pathway can inhibit terminal differentiation and hypertrophy in chondrocytes. However, TGF- β activity can also contribute to the pathogenesis and progression of OA. For example, TGF- β signaling induces osteophyte formation in animal models. In aging cells and cells in which the ratio of the TGF- β receptors ALK1 and ALK5 is altered, TGF- β can also have opposing effects such as activating MMP-13 and inducing terminal hypertrophic differentiation in chondrocytes.¹²³

BMPs are structurally related to TGF- β but generally activate a different set of receptors and intracellular signaling molecules. BMPs influence all stages of embryonic chondrogenesis and can promote chondrogenic differentiation of adult MSCs.¹²⁴ Recent genetic evidence suggests that impaired BMP signaling affects OA susceptibility, with the most progress reported for BMP-14 (GDF-5).^{125,126} There is good evidence that a reduction of BMP-7 (OP-1) is evident in osteoarthritic cartilage,¹²⁷ with possible regulation occurring through both inhibitory microRNA¹²⁸ and promoter methylation.¹²⁹ Supplementation of BMP-7 in joints reduces experimental arthritis in animals and was proven safe in a phase I clinical trial, with no findings of ectopic bone formation in the enrolled patients during the study.¹³⁰ However, as described for TGF- β earlier, BMP signaling through certain receptors can also enhance terminal differentiation and hypertrophy in chondrocytes, processes that are hallmarks of OA progression.

Figure 98-2 Schematic of pathogenic mechanisms of osteoarthritis. Mechanical stress initiates altered metabolism characterized by the release of matrix metalloproteinases (MMPs), proinflammatory cytokines, and mediators such as nitric oxide (NO) and prostaglandin E₂ (PGE₂). Cartilage breakdown products play a role by stimulating the release of cytokines from synovial lining cells and by inducing MMP production by chondrocytes. Perpetuation of cartilage damage is amplified by the autocrine and paracrine actions of interleukin (IL)-1 β and tumor necrosis factor (TNF) produced by chondrocytes. PA, plasminogen activator; TGF- β , transforming growth factor- β ; TIMPs, tissue inhibitors of metalloproteinases.

Catabolic Factors and Cartilage Degradation

In addition to new matrix synthesis, cartilage remodeling also involves a degree of proteolysis. This occurs via the induction of an array of proteases, particularly matrix metalloproteinases (MMPs). In OA, the cytokines IL-1 and TNF stimulate the synthesis and secretion of many proteases and MMPs (Figure 98-2).¹⁰⁵ IL-1 is synthesized by mononuclear cells (including synovial lining cells) in the inflamed joint and by chondrocytes as an autocrine activity.¹³¹⁻¹³³ The enzymes stimulated by IL-1 and TNF include latent collagenase, latent stromelysin, latent gelatinase, aggrecanase, and tissue plasminogen activator (TPA).¹³⁴⁻¹³⁷ Plasminogen is either synthesized by the chondrocyte or enters the matrix by diffusion from the synovial fluid. TPA converts plasminogen to plasmin, a serine proteinase that can activate latent cartilage-degrading enzymes. A downstream mediator of IL-1- and TNF-induced cartilage degradation that is gaining increasing attention is hypoxia-inducible factor 2 α (Hif2 α).^{138,139} Hif2 α is a transcription factor strongly upregulated in OA cartilage and mouse models of OA. It directly induces the expression of many cartilage-degrading enzymes including MMPs 1, 3, 9, and 12, as well as a disintegrin and metalloproteinase with thrombospondin motif (ADAMTS-4) and (indirectly) ADAMTS-5. In addition, a high level of Hif2 α decreases the protective role of autophagy, increases the extent of cell death, and activates the RUNX2 and IHH pathways that further contribute to cartilage matrix degradation. The different classes of proteinases that are activated by these cytokines in OA are discussed in more detail later.

Classes of Proteinases (Metalloproteinases, Aggrecanases, Serine and Cysteine Proteinases)

In OA, the synthesis and secretion of matrix-degrading enzymes by chondrocytes markedly increases.^{104,115,140-142} There are four classes of proteases, which are grouped by the catalytic mechanisms of peptide bond cleavage: metalloproteinases, cysteine proteinases, serine proteinases, and aspartyl proteinases. Of these, the first three have clearly defined roles in the degradation of cartilage during the progression of OA.

Metalloproteinases

Metalloproteinases have an enzymatic site that requires a metal ion (often zinc) for activity. Cartilage contains two families of metalloproteinases, namely ADAMTSs and MMPs. Early cartilage degeneration in OA is most likely the result of metalloproteinase enzymatic activity. Both families of metalloproteinases are upregulated in osteoarthritic cartilage, and both are highly expressed in OA cartilage at lesional sites. As the MMPs and ADAMTSs play major roles in the degradation of cartilage extracellular matrix, several MMPs and ADAMTSs are candidate targets for disease modification.¹⁴³

The control of metalloproteinase activity in OA is complex, with regulation occurring at three different levels: synthesis and secretion, activation of latent enzyme, and inactivation by proteinase inhibitors.¹⁴⁴ Most metalloproteinases are not constitutively expressed, but their transcription is induced after stimulation with cytokine and growth

factor signaling. Once transcribed, the transcript stability and translation of several metalloproteinases are regulated by microRNA (miR). For example, microRNA-27b (miR-27b) regulates MMP-13 expression.¹⁴⁵ Also, miR-140 levels are decreased in OA, which reduces its repression of ADAMTS-5.¹⁴⁶ Several of these miRNAs are controlled by the same cytokines and growth factors that maintain cartilage homeostasis including IL-1 and TGF- β . Although the miR field is still in its infancy, it is already evident that several miRs are involved in the pathogenesis of OA by affecting transcript stability and protein translation. Once translated into proteins, almost all MMPs are expressed as inactive proenzymes (zymogens) that require further processing for full proteolytic activity. Most MMPs contain an N-terminal prodomain that blocks or otherwise inhibits the catalytic site. The primary MMP activators are serine- and cysteine-dependent proteases (e.g., the plasminogen/plasmin cascade or furin-like proprotein convertases and cathepsin B, respectively), as well as membrane-type MMPs.^{118,147,148} Activated MMPs can then be inactivated nonspecifically by $\alpha 2$ macroglobulin and with more specificity by the tissue inhibitor of metalloproteinase (TIMP) family of proteins.

MMPs have historically been further divided into three groups on the basis of their substrate specificities; collagenases cleave across all three chains of the native triple-helical collagens, whereas gelatinases preferably cleave denatured collagen and stromelysins have much broader substrate specificities.¹⁴⁹ However, there is considerable overlap in substrates between these classifications; for example, MMP-1 (interstitial collagenase), MMP-3 (stromelysin 1), and MMP-13 (collagenase-3) are all capable of cleaving aggrecan core protein.¹⁵⁰ MMPs can degrade other cartilage extracellular matrix molecules in addition to collagen. If combined with plasmin, which has the capability of activating many MMPs, MMPs can rapidly destroy cartilage altogether.

Collagenases

Collagenases typically make the first cleavage in triple-helical collagen, allowing its further degradation by other proteases. Degradation of collagens is thought to be the first irreversible step in the pathogenesis of OA because it significantly reduces the mechanical properties of cartilage. The best-studied MMPs capable of cleaving native collagens are MMP-13 and MMP-1, although MMP-8 and MMP-28 are also involved in breaking down type II collagen. Of the MMPs that degrade native collagen, MMP-13 may be the most important in OA because it preferentially degrades type II collagen.¹⁵¹ Mice deficient in MMP-13 resist developing OA and have reduced cartilage erosion even after proteoglycan loss.¹⁵² Expression of MMP-13 greatly increases in OA¹⁵³; overall collagenase activity also markedly increases in human osteoarthritic cartilage cultures, suggesting that it is a major factor in OA progression and cartilage matrix degradation.^{154,155} The resultant collagen fragments may then be susceptible to further cleavage by such other enzymes as MMP-2 (gelatinase A), MMP-9 (gelatinase B), MMP-3, and cathepsin B (a cysteine proteinase).

Aggrecanases

The aggrecanases are metalloproteases that belong to a family of extracellular proteases known as ADAMTS.¹⁵⁶ Two aggrecanases, ADAMTS-4 and ADAMTS-5, appear to be major enzymes in cartilage degradation in arthritis.¹⁵⁷ The roles of these enzymes appear reversed in human and mouse OA—whereas ADAMTS-4 is predominantly associated with aggrecan degradation in human OA, in mouse models of OA ADAMTS-5 is more important.¹⁵⁸⁻¹⁶⁰ Recombinant ADAMTS-4 and ADAMTS-5 cleave aggrecan at five distinct sites along the core protein, and all resultant fragments have been identified in cartilage explants undergoing matrix degradation. The G1 region of aggrecan is highly resistant to proteases; however, a glutamate-alanine bond within the extended region between G1 and G2 is remarkably susceptible to proteolytic degradation.¹⁶¹ Aggrecanase proteolytic activity can be modulated by altered expression, by activation by proteolytic cleavage at a furin-sensitive site, by binding to the aggrecan substrate through the C-terminal thrombospondin motif, by activation through post-translational processing of a portion of the C-terminus, and by inhibition of activity by the endogenous inhibitor, tissue inhibitor of metalloproteinase 3 (TIMP-3). ADAMTS-4 and ADAMTS-5 activity is also detected in joint capsule and synovium and may be upregulated in arthritic synovium at either the message level or through posttranslational processing. In addition to ADAMTS-4 and ADAMTS-5, several MMPs are also capable of cleaving aggrecan in vitro (MMP-1, MMP-2, MMP-3, MMP-7, MMP-8, MMP-9, MMP-13, and MMP-28), as are ADAMTS-1, ADAMTS-8, ADAMTS-9, and ADAMTS-15.¹⁶² It has been shown that ADAMTS-7 and ADAMTS-12 both bind to and degrade COMP (a prominent noncollagenous protein in cartilage) and that the latter is highly upregulated in osteoarthritic cartilage.^{163,164} ADAMTS-4, ADAMTS-19, and ADAMTS-20 also have been shown to degrade COMP in vitro; however, their in vivo activity in osteoarthritis has yet to be determined.^{165,166}

A specific hyaluronidase has not been found in articular cartilage matrix, but one or several lysosomal enzymes that can cleave both hyaluronic acid and chondroitin-6-sulfate have been implicated.¹⁴⁷ There are six or seven potential hyaluronidases in the human genome, and of these, hyaluronidase-1, hyaluronidase-2, hyaluronidase-3, and PH-20 are likely to be active in cartilage.¹⁶⁷ However, experimental evidence to date suggests that these enzymes are either exclusively lysosomal or can exist both in the lysosome and at the plasma membrane. Thus although there is convincing evidence of extracellular degradation of hyaluronan, the precise role of the hyaluronidases in this process has not yet been clearly identified. The decrease in chondroitin sulfate chain length in osteoarthritic cartilage may be due to digestion by synovial fluid hyaluronidase, which may diffuse into the matrix as its permeability increases.¹⁰³ Evidence to support this theory is the finding that the hyaluronic acid concentration in OA cartilage is low, even though its rate of synthesis is considerably greater than normal.^{104,115} These degradative enzymes serve to disrupt the proteoglycan aggregate. The early result of the MMP-induced tissue degradation is thinning of the collagen fibers,

loosening of the tight collagen network, and the consequent cartilage matrix swelling seen in OA.

Enzyme Inhibitors (Tissue Inhibitor of Metalloproteinases, Plasminogen Activator Inhibitor-1)

The balance of active and latent enzymes is controlled to some extent by at least two enzyme inhibitors: tissue inhibitor of metalloproteinases (TIMP) and plasminogen activator inhibitor-1 (PAI-1).^{141,168,169} TIMP and PAI-1 are synthesized in increased amounts under the regulation of transforming growth factor- β .¹⁷⁰⁻¹⁷² If insufficient concentrations of or degraded TIMP or PAI-1 are present in the matrix along with active enzymes, then increased matrix degradation occurs. Expression profiling of all known members of the MMP, ADAMTS, and tissue inhibitor of metalloproteinases (TIMP) gene families in normal cartilage and cartilage from patients with OA has revealed that several members are regulated in OA. Genes that showed increased expression in OA were MMP-2, MMP-9, MMP-13, MMP-16, MMP-28, ADAMTS-2, ADAMTS-12, ADAMTS-14, ADAMTS-16, and TIMP-3 (all at $P < .05$). Genes with decreased expression in OA were MMP-1, MMP-3, MMP-10; ADAMTS-1, ADAMTS-5, ADAMTS-9, and ADAMTS-15; and TIMP-1 and TIMP-4.¹⁷³ These results illustrate the complexity of the events that occur within the extracellular matrix regarding regulation of tissue-degrading enzymes.

Alterations in Matrix Synthesis

Much of what is known about changes in the extracellular matrix in early OA comes from animal models (e.g., the rabbit partial meniscectomy model, the canine anterior cruciate ligament-deficient model).^{174,175} These animal models represent secondary OA, produced by internal derangement of the joint, and therefore may not precisely simulate the state of affairs in primary OA. In a recent review, models for spontaneous osteoarthritis were reviewed and their preclinical utility was compared.¹⁷⁶ Of particular interest is an iodoacetate model, validated as the first pain model of osteoarthritis, in which intra-articular injection of iodoacetate in rats has been shown to lead to cartilage degeneration associated with pain and manifesting as time- and concentration-dependent alterations in hindlimb weight bearing.^{177,178} That not all animal models of osteoarthritis are equivalent becomes clear when one considers the differences in therapeutic response between young and old animals and between spontaneous and surgical models.¹⁷⁹

In the dog model, the first alteration seen within days after joint destabilization is an increase in cartilage water content.¹⁸⁰ Initially, water content increases locally, in the tibial plateau and femoral condyle cartilage, but it soon spreads to the entire joint cartilage. Proteoglycans are more readily extractable from the matrix of experimental animals than from that of controls, and this is reflected in the serum biomarker profile after acute injury in patients.¹⁸¹ These matrix changes are also seen in spontaneously occurring dog and steer OA and in experimentally induced rabbit OA.^{180,182,183} The increase in water content in osteoarthritic cartilage is due to loss of the collagen network's elastic

restraint, enabling the hydrophilic proteoglycans to swell more than normally.¹⁸⁴ In early-stage OA, proteoglycan concentration may increase and the cartilage may consequently become thicker than normal and exhibit increased staining for proteoglycans.¹⁸⁵⁻¹⁸⁷ Shortly after the increase in cartilage water, newly synthesized proteoglycans are characterized by a higher proportion of chondroitin sulfate and a lower proportion of keratan sulfate and proteoglycan aggregation is impaired.^{175,180} These abnormal changes in extracellular matrix occur before fibrillation or any other gross morphologic changes are evident and result in a generalized decrease in stiffness that occurs in grossly normal cartilage adjacent to fibrillated areas.¹⁸⁸ As OA progresses, focal cartilage ulcerations develop. Proteoglycan loss is accompanied by a decrease in its ability to aggregate, persistence in abnormal glycosaminoglycan composition, and a decrease in chondroitin sulfate chain length. Once proteoglycan loss reaches a critical threshold, water content, which initially increased, falls below normal.¹⁸⁹

Chondrocyte Senescence

The term *senescence* was originally coined to describe the replicative limit of primary cells cultured in vitro, and the concept has evolved to include premature senescence or senescence-like changes in differentiated postmitotic cells. Senescent cells have a unique phenotype that affects both the proteins expressed by senescent cells and their responses to extracellular stimuli. Furthermore, the impact of senescence is not limited to the cells undergoing senescence; rather, the senescent cells have an impact on surrounding cells through the paracrine effects of the altered protein secretions.¹⁹⁰

Premature chondrocyte senescence in OA is thought to be enhanced by oxidative injury.¹⁹¹ The inflammatory cytokines IL-1 β and TNF that are active in OA induce oxidative stress in chondrocytes, thereby contributing to the potential for oxidative injury that leads to senescence. Oxidative injury is also induced with excessive mechanical shear and injurious loading of explants, and this may contribute to the accumulation of senescent chondrocytes in aged cartilage.¹⁹² TGF- β can influence both growth arrest and senescence in cultured cells, and senescent cells can overexpress TGF- β , but this effect has mostly been demonstrated in endothelial cells and not cells of mesenchymal origin. In summary, although it is clearly evident that many of the cellular mechanisms controlling senescence are also active in disease progression including OA, a causal link between senescence and OA has yet to be identified.

BIOMECHANICS AND DISEASE MECHANISMS OF OSTEOARTHRITIS

Biomechanical Changes

Two long-standing biomechanical theories of the pathogenesis of OA hold that mechanical stresses injure chondrocytes, causing them to release degradative enzymes, and that mechanical stresses initially damage the collagen network (as opposed to the cells per se)^{193,194}—in either case, the result is that matrix breaks down. Extracellular matrix breakdown in osteoarthritic cartilage leads to (1) loss of

compressive stiffness and elasticity, resulting in greater mechanical stress on chondrocytes; and (2) an increase in hydraulic permeability, resulting in loss of interstitial fluid during compression and increased diffusion of solutes through the matrix (including the movement of degradative enzymes and their inhibitors). One important consequence is disruption of normal fluid film joint lubrication and loading dynamics due to alterations in inflammatory synovial fluid.¹⁹⁵⁻¹⁹⁷ Joint friction, wear, lubrication, and contact mechanics are further negatively affected by the loss of cartilage proteoglycans and superficial zone protein (also called *lubricin*).¹⁹⁸⁻²⁰²

Response of Cartilage to Mechanical Injury

The response of normal articular cartilage to injury typically results in suboptimal repair; these injuries can often result in secondary OA.^{203,204} Articular cartilage produces a repair tissue with neither the original structure nor properties of normal cartilage.²⁰⁵⁻²⁰⁸ Chondrocytes in areas surrounding an injured zone are unable to migrate, proliferate, repopulate, or regenerate repair tissue with similar structure, function, and biomechanical properties of normal hyaline cartilage.^{189,205,209}

That articular cartilage lacks regenerative power has a long history of documentation.²¹⁰ In 1851 Redfern reported that articular cartilage wounds healed with fibrous tissue, which he believed arose from chondrocyte intercellular substance.²¹¹ Fisher and Ito in the 1920s proposed that cartilage repair is effected by fibrous tissue resulting from proliferation of cells from bone marrow, synovial membrane, and occasionally surrounding articular cartilage.^{212,213} It was later observed that the fibrous tissue regenerate subsequently transforms into fibrocartilage, with occasional foci of imperfect hyaline cartilage.²¹⁴⁻²¹⁷ The common findings of these investigators were that articular cartilage lacks regenerative potential and that the regenerative fibrous tissue and fibrocartilage tissue must have originated from undifferentiated mesenchymal tissue arising from bone marrow, synovium, or the superficial layer of articular cartilage.²¹⁰

One reason the reparative process of cartilage significantly differs from those of other tissues is that it is avascular. The healing response in vascularized tissues consists of three main phases: necrosis, inflammation, and repair.^{203,208} Cartilage undergoes the initial phase of necrosis in response to injury, although typically less cell death occurs than in vascularized tissues because of chondrocytes' relative insensitivity to hypoxia.^{203,208} The inflammatory phase, primarily mediated (in other tissues) by the vascular system, is largely absent in partial-thickness injuries (i.e., lesions that do not cross the tidemark), and the repair phase is severely limited given the lack of vascularity and a preceding inflammatory response. Thus no local hyperemia results, no fibrin network is produced, no subsequent clot develops to act as a scaffold for the ingrowth of repair tissue, no mediators nor cytokines are released that can stimulate cellular migration and proliferation, and no inflammatory cells, which have mitotic and reparative potential, are recruited.^{189,208} In lesions that do not cross the tidemark, the burden of repair falls on the chondrocytes²⁰⁸ in a process that has been termed *intrinsic repair*.²¹⁸ Although fetal cartilage is capable of mitotic activity and replication, adult chondrocytes have little potential

for replication and intrinsic repair.^{216,217} Articular cartilage lesions that cross the tidemark may undergo extrinsic repair via differentiation and proliferation of mesenchymal stem cells from para-articular connective tissues; typically, however, a fibrocartilaginous regenerate results.²¹⁸

There are three categories of articular cartilage injury: (1) microdamage or repetitive trauma to the matrix and cells; (2) partial-thickness or superficial injuries or chondral fractures, articular surface injuries that do not penetrate the subchondral plate; and (3) osteochondral (full-thickness or deep penetrating) injuries, which extend through the tidemark and into the underlying subchondral bone.^{203,205,208} The host response to each type of injury differs in both timing and quality of repair.

Microdamage to the chondrocytes and/or extracellular matrix without gross disruption of the articular surface can be caused by a single severe impact or repetitive blunt trauma.^{203,205,208} Repetitive loading of rabbit cartilage produces a surface loss of proteoglycans and an increase in chondrocyte metabolic activity.²¹⁹ Proteoglycans become more easily extractable from the articular cartilage, with a greater percentage of nonaggregated forms.¹⁸⁹ The cellular, metabolic, and biochemical changes after repetitive blunt trauma resemble those in the early stages of OA: increased hydration; cellular degeneration and/or death; disruption of the collagen ultrastructure resulting in marked variation in the size and arrangements of fibers, fissuring and ulceration of the articular surface, thickening of the subchondral bone, and softening of the cartilage with loss of its compressive and tensile stiffness.^{189,205,220-223} Trauma induces the release of degradative enzymes and proinflammatory factors (e.g., nitric oxide, TNF, IL-1) that frequently cause degradation of the surrounding matrix.^{219,224,225} Eventually the material properties of the cartilage are altered—cartilage matrix thins and subchondral bone stiffens—which in turn often accelerate the degenerative process.¹⁸⁹ The point at which accumulated microdamage becomes irreversible is unknown, although it has been demonstrated that lost proteoglycans and matrix components may be restored if damage to chondrocytes and the collagen network is limited and the repetitive trauma halted.²⁰⁵

Necrosis of neighboring chondrocytes follows chondral fractures and superficial lacerations, injuries that do not cross the tidemark.^{203,208,226} Within 48 to 72 hours, surviving chondrocytes bordering the defect exhibit increased synthesis rates of extracellular matrix molecules and type II collagen, sometimes accompanied by cell proliferation and formation of clusters or clones in the periphery of the injured zone.^{189,208,226,227} The increased metabolism and mitotic activity is transient, however, and is followed by a fall in metabolic rate back to normal levels, typically resulting in a suboptimal repair.^{189,208} Chondrocytes proliferating on the border of the injured zone do not migrate into the defect, which remains unfilled by the newly synthesized matrix.^{189,205,209} In some cases, superficial lacerations in otherwise normal joints may not progress to full-thickness loss of cartilage or OA.¹⁸⁹

Lesions that cross the articular cartilage tidemark and disrupt the underlying subchondral plate elicit the three-phase repair response normally encountered in vascularized tissues. A hematoma forms in the defect that becomes organized into a fibrin clot, activating an inflammatory response.

Transformation of the fibrin clot into vascular fibroblastic repair tissue^{208,227} is accompanied by release of cytokines important in stimulating a repair response (e.g., TGF- β , platelet-derived growth factor, insulin-like growth factor, BMPs).²⁰⁶ These cytokines help set in motion the recruitment, proliferation, and differentiation of undifferentiated cells into a fibrin network that serves as a scaffold for fibrocartilaginous repair tissue.^{206,228,229} The origin of these mesenchymal stem cells has been determined to be the underlying bone marrow rather than the adjacent residual articular surface.^{227,229,230} These cells progressively differentiate into chondroblasts, chondrocytes, and osteoblasts and synthesize cartilage and bone matrices. At 6 to 8 weeks postinjury, the repair tissue contains a high proportion of chondrocyte-like cells surrounded by a matrix consisting of proteoglycans and type II collagen, with a lesser amount of type I collagen.²³⁰⁻²³² Cells in the deeper layers of the defect differentiate into osteoblasts and subsequently undergo endochondral ossification to heal the subchondral bone defect.¹⁸⁹

This regenerative tissue eventually undergoes a transformation to a more fibrocartilaginous repair accompanied by a shift in the synthesis of collagen from type II to type I.^{209,226,228,229,232} Typically, within 1 year from injury, the repair tissue resembles a mixture of fibrocartilage and hyaline cartilage, with a substantial component (20% to 40%) of type I collagen.²³¹ The size of the osteochondral defect is an important factor in the quality of repair; as a general rule, the smaller the defect, the better the repair.²³³ Depending on the joint, there exists a critical size defect that will not repair. Fibrocartilaginous repair is susceptible to early degenerative changes because it lacks the biomechanical properties to withstand normal physiologic joint loads.^{229,231}

Mechanotransduction and Gene Expression

Chondrocytes can sense and respond to mechanical stimuli via several regulatory pathways (e.g., upstream signaling, transcription, translation, post-translational modification, vesicular transport).²³⁴ Chondrocytes can remodel extracellular matrix in response to alterations in functional demand, as physical forces influence the synthesis, assembly, and degradation of the extracellular cartilage matrix. High magnitude or duration loads can also cause chondrocyte death and collagen damage, and chondrocytes in the superficial zone appear to be more vulnerable to load-induced injury than those in the middle and deep zones.^{235,236} Normal stimuli help chondrocytes maintain the extracellular matrix; abnormal stimuli can disrupt this balance.

Mechanotransduction influences the cell-mediated feedback between physical stimuli, the molecular structure of newly synthesized matrix molecules, and the resulting biomechanical tissue properties.²³⁷ Cell-matrix interactions via integrins are believed to be one of the important mediators in mechanotransduction in chondrocytes. In a study on the expression of COMP to long-term cyclic compression, it was found that uniaxial unconfined dynamic compression significantly upregulated COMP expression, which could be blocked by incubation with anti- $\alpha 1$ -integrin antibodies.²³⁸ Studies of bovine articular cartilage explants showed that cyclic loading increased protein synthesis by as much as

50% above free-swelling controls and had an inhibitory influence on proteoglycan synthesis, whereas static compression reduced biosynthetic activity.²³⁹ Fibronectin and COMP were the most affected noncollagenous extracellular proteins; static compression caused a significant increase in fibronectin synthesis versus free-swelling control levels, and cyclic compression caused a significant increase in synthesis of COMP and fibronectin.

Human articular chondrocytes use the $\alpha 5 \beta 1$ integrin as a mechanoreceptor. Mechanical stimulation initiates a signal cascade involving stretch-activated ion channels, the actin cytoskeleton, and focal adhesion complex molecules.²⁴⁰ The result is an anabolic response, manifested by increased aggrecan and decreased MMP-3 expression. Mechanical stimulation also activates Rho and Rho kinase pathways, which are linked to changes in the actin cytoskeleton.^{241,242} Stimulation of the Rho/ROCK pathway in this context is an anabolic stimulus that leads to nuclear translocation and activation of Sox9, which is a “master regulator” of cartilage gene expression.²⁴³ Indian hedgehog (Ihh) protein is a key signaling molecule that controls chondrocyte proliferation and differentiation and may also be an essential mediator of mechanotransduction in cartilage: Cyclic mechanical stress was shown to induce Ihh expression by chondrocytes.²⁴⁴

Dysregulation of these anabolic pathways is thought to contribute to the progression of OA. For example, although the $\alpha 5 \beta 1$ integrin is also mechanosensitive in OA chondrocytes, the downstream signaling pathways differ, leading instead to increased cartilage breakdown.²⁴⁵ Integrins and integrin-associated signaling pathways are at least partly regulated by mechanical stimulation by activation of plasma membrane apamin-sensitive Ca^{2+} -activated K^{+} channels; the result is membrane hyperpolarization after cyclic mechanical stimulation.²⁴⁶ Chondrocytes from normal articular cartilage exhibit membrane hyperpolarization response to cyclic pressure-induced strain, whereas chondrocytes from osteoarthritic cartilage respond by membrane depolarization and exhibit no changes in aggrecan or MMP-3 messenger RNA following mechanical stimulation.^{247,248} The different signaling pathways responding to mechanical stimulation in healthy versus OA chondrocytes may affect the disease outcome.

In addition to cell and matrix deformation, fluid flow is also sensed by chondrocytes. A study using a tissue shear-loading model to uncouple fluid flow from cell and matrix deformation demonstrated that deformation of cells and pericellular matrix alone stimulated protein and proteoglycan synthesis.²⁴⁹

ABNORMALITIES OF BONE

Osteophyte Formation

Osteophytes—bony proliferations at the joint margins and in the floor of cartilage lesions—are in part responsible for the pain and restriction of joint movement in OA. Human osteoarthritic joint osteophytes synthesize cartilage with significant amounts of type I collagen and nonaggregating proteoglycans.²⁵⁰ In experimentally induced OA, osteophytes may develop even though the articular cartilage appears grossly normal.²⁵¹ Osteophytes may result

from penetration of blood vessels into the basal layers of degenerating cartilage or as a result of abnormal healing of stress fractures in the subchondral trabeculae near the joint margins.^{252,253} In the OA dog model, periarticular osteophyte formation begins in the marginal zone, where synovium merges with periosteum and articular cartilage, as early as 3 days after induction of knee instability.²⁵⁴ Bony proliferation may result from venous congestion; in human hip OA, phlebography has demonstrated the formation of medullary varices, presumably due to changes in the medullary sinusoids, which may be compressed by subchondral cysts and thickened subchondral trabeculae.^{255,256} Subchondral cysts in OA may be created by entry of synovial fluid under pressure through defects in the cartilage or may develop in necrotic areas of subchondral bone.²⁵⁷ The increased venous pressure caused by the cysts and remodeled trabeculae may account for some of the pain in OA. Immobilization and glucocorticoids (but not bisphosphonates) have been shown to decrease the size and prevalence of osteophytes in experimental models of OA.²⁵⁸⁻²⁶¹

Subchondral Bone Sclerosis

Increased remodeling and hardening of subchondral bone is evident early in osteoarthritis and can sometimes be detected before loss of cartilage thickness is evident radiologically.²⁶² An advancing tidemark of calcified cartilage is observed in OA, which changes the mechanical interface between subchondral bone and cartilage and is associated with increased subchondral vascularity. The increased calcification results in a thinning cartilage layer, which increases the mechanical stress in the adjacent cartilage. In combination with subchondral bone sclerosis, the altered mechanical environment and rapid bone remodeling may be contributing factors in cartilage degradation and OA pathogenesis.

Bone Marrow Lesions

Bone marrow lesions (detectable by MRI) are associated with OA, and studies suggest that they contribute to the pain felt by OA patients.²⁶³ The presence of bone marrow lesions is predictive of OA progression, the development of cartilage defects and degradation, and the need for joint replacement.²⁶⁴ The relationship between bone marrow lesions and cartilage degeneration in OA is still under investigation. For example, a longitudinal study also found that the presence of cartilage defects predicts progression of bone marrow lesions. The study authors suggest that it “remains unclear whether bone marrow lesions precede, accompany, or follow cartilage damage and volume loss in OA.”²⁶⁴

Fibrosis and necrosis of the underlying bone marrow are common histologic features of the lesions visible by MRI, as are high bone turnover, altered trabecular structure, and edema. Unlike cartilage loss, bone marrow lesions are not a permanent structural change in OA. Several reports demonstrate that these lesions can resolve or at least regress, although it is more commonly observed that bone marrow lesion scores increase over time.²⁶⁵ It has been postulated that edema-like lesions are less severe and reversible, whereas more advanced fibrotic and necrotic lesions are not.²⁶⁶ There is a possibility that synovial fluid entering the

subchondral bone marrow through intra-articular defects leads to an altered growth factor and cytokine environment that affects bone turnover. These findings suggest that there may be an altered biomechanical property of the subchondral tissues, which in turn would affect the biomechanical stresses experienced by the adjacent cartilage.

ROLE OF INFLAMMATORY MEDIATORS IN DISEASE PROGRESSION

Although levels of inflammatory cytokines such as IL-1, IL-6, and TNF are elevated in the serum of patients with knee osteoarthritis,²⁶⁷ these and other classic inflammatory mediators are activated within the joint tissues themselves during the course of OA. These cytokines autocatalytically stimulate their own production and induce chondrocytes to produce proteases, chemokines, nitric oxide, and eicosanoids such as prostaglandins and leukotrienes. The action of these inflammatory mediators within cartilage is predominantly to drive catabolic pathways, inhibit matrix synthesis, and promote cellular apoptosis. Thus although osteoarthritis is not conventionally considered an inflammatory disease, “inflammatory” mediators from the affected tissues perpetuate disease progression and therefore represent potential targets for disease modification.

Inflammatory Molecules Produced by Articular Cartilage

Cytokines and Chemokines

A characteristic feature of established osteoarthritis is the increased production of proinflammatory cytokines such as IL-1 β and TNF by articular chondrocytes. Both IL-1 β and TNF exert comparable catabolic effects on chondrocyte metabolism, decreasing proteoglycan collagen synthesis and increasing aggrecan release via the induction of degradative proteases.^{142,268-273} IL-1 β and TNF also induce chondrocytes and synovial cells to produce other inflammatory mediators such as IL-8, IL-6, nitric oxide, and prostaglandin E₂. The actions of both cytokines are in part mediated by the activation of the transcription factor nuclear factor κ B (NF κ B), which further increases their own expression and that of other catabolic proteins such as inducible nitric oxide synthase and COX-2, thus creating an autocatalytic cascade that promotes self-destruction of articular cartilage²⁷⁴⁻²⁷⁶ (Figure 98-3). Mounting evidence suggests that NF κ B mediates chondrocytes' proinflammatory stress responses in OA and also controls these cells' differentiation, making NF κ B activating factors attractive OA therapeutic targets for many reasons.²⁷⁷

IL-1 β and TNF are both synthesized intracellularly as precursors, converted through proteolytic cleavage to their mature forms by caspases—membrane-bound IL-1 β -converting enzyme (ICE) and TNF-converting enzyme (TACE)—and released extracellularly in their active forms.²⁷⁸ The expression of both ICE and TACE has been shown to be upregulated in OA cartilage.²⁵¹⁻²⁵³ Inhibitors of both ICE and TACE are of interest as future therapeutic small-molecule antagonists of downstream IL-1 β and TNF expression, respectively.

Figure 98-3 Immunostaining of osteoarthritic cartilage specimen for inducible nitric oxide synthase (A) and interleukin-1 β (B). Note intense staining of chondrocytes in the superficial zones for both inflammatory proteins. (From Melchiorri C, Meliconi R, Frizziero L, et al: *Enhanced and coordinated in vivo expression of inflammatory cytokines and nitric oxide synthase by chondrocytes from patients with osteoarthritis*, *Arthritis Rheum* 41:2165–2174, 1998.)

The actions of IL-1 are dependent on the engagement of two specific cell surface receptors (IL-1Rs), designated type I and type II. The type I receptor, which spans the plasma membrane, is responsible for signal transduction, whereas the type II receptor is a “decoy” receptor, expressed at the cell membrane but unable to signal. A relative deficit of the ratio of IL-1Ra (the competitive inhibitor to the IL-1/IL-1R complex) to IL-1 has been described in OA synovial tissue, which may permit increased IL-1 activity.^{279,280} Addition of IL-1Ra, or soluble type I and II IL-1 receptors, to OA explant cultures blocks prostaglandin E₂ (PGE₂) synthesis, collagenase production, and nitric oxide (NO) production^{273,281}; addition of these antagonists in culture also results in an increase in aggrecan content, likely by inhibiting degradation of newly synthesized molecules.²⁸² One recent study showed that chondrocytes with abnormal morphology, from macroscopically intact cartilage representative of early OA, demonstrated increased levels of cell-associated IL-1 and loss of type VI collagen.²⁸³

Encouraging results with IL-1Ra have also been reported in vivo, where gene therapy or the intra-articular administration of IL-1Ra has been shown to retard the progression of OA in experimental animal models.^{284,285} Other lines of evidence also point to IL-1 β as an essential link in the pathogenesis of cartilage damage including proteoglycan loss by intra-articular injection of IL-1.²⁸⁴ Clinical trials using IL-1 β antagonists in OA are few and have been inconclusive. One multicenter trial with double-blinded doses of intra-articular IL-1Ra to 14 OA patients resulted in decreased pain without significant adverse events or acute injection reactions.²⁸⁶ No long-term studies of structure-modifying effects of such therapies have been reported, however.

Osteoarthritic cartilage is also the site of increased production of both CXC and CC chemokines. These include IL-8, monocyte chemoattractant protein-1 (MCP-1), and RANTES (regulated on activation, normal T-cell expressed and secreted; aka CCL5) chemokine, as well as the receptors CCR-2 and CCR-5.²⁸⁷⁻²⁸⁹ The expression of chemokines is low or undetectable in normal chondrocytes unless stimulated with cytokines such as IL-1 or IL-17.²⁹⁰ Chemokines are detected by immunohistochemistry in the superficial and midzones of the tissue, as has been demonstrated

for such other inflammatory mediators as inducible nitric oxide synthase (iNOS), IL-1 β , and TNF.²⁸⁸ RANTES induces expression of its own receptor, CCR-5, suggesting an autocrine/paracrine pathway of the chemokine within the cartilage. MCP-1 and RANTES promote chondrocyte catabolic activities including induction of nitric oxide synthase, increased MMP-3 expression, inhibition of proteoglycan synthesis, and enhancement of proteoglycan release.^{288,291} Consistent with these effects, treatment of normal articular cartilage with RANTES increases the release of glycosaminoglycans and profoundly reduces the intensity of safranin O staining.²⁸⁸

Proteinases

A presumed key action of cytokines and chemokines produced in osteoarthritis is to promote cartilage proteolysis via the induction of a wide array of proteases, in particular MMPs. The two main families of MMP enzymes are (1) the collagenases that break down type II collagen (especially MMP-1, MMP-8, MMP-13, and MMP-28) and proteoglycans (MMP-3, which also cleaves pro-MMPs into their active forms) and (2) the aggrecanase (ADAMTS) family, which mediate aggrecan degradation in cartilage.^{173,184} Both families of MMPs are expressed in OA cartilage at lesional sites, where it is presumed that they play a major role in degradation of the extracellular matrix. A recent comprehensive analysis of specific metalloproteinases that are overexpressed by OA cartilage and synovium has revealed several MMPs and ADAMTSs that may be candidates as targets for disease modification.¹⁴³ Among the most interesting is MMP-13, which is overexpressed in murine and human OA cartilage and is the most efficient protease capable of cleaving type II collagen.^{228,292} Similarly, the aggrecanase ADAMTS-5 has surfaced as the aggrecanase required for aggrecan loss in experimental OA¹⁵⁹ and inflammatory joint disease.¹⁶⁰ It has been demonstrated that mice lacking ADAMTS-5 are protected from developing OA.¹⁵⁹

The expression and degradation of noncollagenous proteins and nonaggregating proteoglycans are also altered in OA cartilage and may have a direct or indirect effect on modulating the catabolic state of the chondrocyte.²⁹³ These

groups of molecules are likely to have important structural and/or biologic functions.^{294,295} From their interactions with other extracellular matrix constituents, they can influence the supramolecular assembly of the cartilage matrix and as a result affect the physical properties of the tissue; by interacting directly with chondrocytes and/or neighboring cells, they can provide biologic signals on matrix properties and thereby influence cellular function.²⁹⁶

Nitric Oxide

Nitric oxide, produced by the inducible isoform of nitric oxide synthase (iNOS), is a major catabolic factor produced by chondrocytes in response to proinflammatory cytokines such as IL-1 β and TNF.²⁸⁷ Considerable evidence indicates that the overproduction of nitric oxide by chondrocytes plays a role in the perpetuation of cartilage destruction in OA²⁹⁷⁻²⁹⁹ (Figure 98-4). Increased concentrations of nitrites have been demonstrated in the synovial fluid of patients with OA, and iNOS has been demonstrated in OA synoviocytes and chondrocytes by in situ hybridization and immunohistochemistry.^{300,301} Although normal cartilage does not express iNOS or produce nitric oxide without stimulation by cytokines such as IL-1, OA cartilage explants spontaneously produce large amounts of nitric oxide²⁹⁷; iNOS is also upregulated from chondrocytes by cartilage compression.^{302,303}

Nitric oxide exerts multiple effects on chondrocytes that promote articular cartilage degradation.³⁰⁴ These include (1) inhibition of collagen and proteoglycan synthesis³⁰⁴; (2) activation of metalloproteinases³⁰⁵; (3) increased susceptibility to injury by other oxidants (e.g., H₂O₂)³⁰⁶; and (4) apoptosis.³⁰⁴ Several studies have implicated nitric oxide as an important mediator in chondrocyte apoptosis, a feature common in progressive OA.^{306,307} Immunohistochemistry of joint tissue obtained from patients with OA reveals

colocalization of iNOS protein and apoptosis in articular cartilage cells.³⁰⁸ There is evidence that apoptosis results from the formation of peroxynitrite, a toxic free radical produced by the reaction of nitric oxide and superoxide anion. Peroxynitrite reacts with tyrosine residues on proteins, which can be detected by antibodies to nitrotyrosine. Immunostaining of OA cartilage reveals that chondrocytes that are highly positive for IL-1 β also stain for nitrotyrosine, consistent with overproduction of peroxynitrate and oxidative damage.³⁰¹ The importance of nitric oxide has been corroborated in animal models of OA. In the Pond-Nuki canine model, the inhibition of nitric oxide reduced the progression of cartilage lesions.³⁰⁹

Transforming Growth Factor- β

In most respects, TGF- α acts as a counterregulatory molecule that opposes the effects of inflammatory mediators in cartilage. TGF- β ₁ has been shown to downregulate proteolytic MMP-1 and MMP-13, as well as IL-1 and TNF receptors on OA chondrocytes.³¹⁰ TGF- β ₂ selectively suppresses the cleavage of type II collagen by collagenases in OA cartilage in culture and limits MMP and proinflammatory cytokine expression.²⁶⁸ Recent studies using the murine knee osteoarthritis model indicate that TGF- β ₃ protects articular cartilage, as histologic staining for this molecule revealed a lack of TGF- β ₃ in damaged cartilage in comparison with normals. Although premature osteophyte chondrocyte clusters express high levels of TGF- β ₃, other data suggest that bone morphogenic protein 2 (BMP-2) is more responsible for the development of late osteophyte development.³¹¹ Of note, TGF- β ₁ may also exert selected catabolic effects via the stimulation of ADAMTS-4 expression.³¹⁰

Hyaluronic Acid

Hyaluronic acid (HA) has been investigated as a marker of cartilage degradation that can be detected in synovial fluid and serum (see *Biomarkers of Osteoarthritis* later),³¹² but it also appears to play a role in limiting the progression of arthritis. A recent study by Karna and colleagues found that HA in vitro counteracts the ability of IL-1 β to inhibit collagen biosynthesis. At the transcriptional and post-transcriptional levels, chondrocyte cultures with IL-1 β upregulated collagen synthesis markers, whereas HA negated this effect.³¹³ The same group found that HA similarly protects against IL-1-induced inhibition of collagen synthesis in human skin fibroblasts at the level of the insulin-like growth factor I receptor.³¹⁴

Prostaglandins

The expression of inducible cyclooxygenase-2 (COX-2) is increased in OA chondrocytes, which spontaneously produce PGE₂ ex vivo.²⁸⁹ The effects of prostaglandins on chondrocyte metabolism are complex, and include enhanced type II collagen synthesis, activation of metalloproteinases, and promotion of apoptosis.³¹⁵ In cartilage explants, IL-1 β induces COX-2 expression and PGE₂ production coordinates with proteoglycan degradation. COX-2 inhibition prevents IL-1 β -induced proteoglycan degradation, which can be reversed by the addition of PGE₂ to cultures.³¹⁶ In

Figure 98-4 Arthroscopic view of osteoarthritic lesion of the femoral condyle (designated chondropathy). Note that proliferative synovitis is localized to the area of the osteoarthritic lesion. (Courtesy Maxime Dougados.)

contrast, *in vitro* evidence has accumulated that selected nonsteroidal anti-inflammatory drugs (NSAIDs) may interfere with proteoglycan synthesis.³¹⁷ Of note, another study concluded that up to 30% of PGE₂ expression in OA synovial tissue stems from the COX-1 pathway.³¹⁸ Whether any differences exist between the effects of COX-1- and COX-2-derived prostaglandins on cartilage metabolism is unknown.

F-spondin

A novel mediator in OA cartilage, F-spondin is a neuronal extracellular matrix glycoprotein that appears to regulate cartilage degradation through the TGF- β and PGE₂ pathways. One recent article reported a sevenfold increase in expression in human OA cartilage and a significant upregulation in knee cartilage surgical specimens from rats with OA. Addition of F-spondin *in vitro* to OA cartilage tissue led to increased levels of activated TGF- β and production of PGE₂, as well as accelerated collagen degradation and reduced proteoglycan synthesis, which are both dependent on these two molecules.³¹⁹

Alterations in Bone

The inflammatory mediators produced by bone in OA are less well understood than those produced by cartilage and synovium. Biomechanical and biochemical factors seem to influence the remodeling, but the underlying pathogenesis has yet to be identified. Nitric oxide plays a role in bone cell function, which could have implications for OA insofar as it contributes to alterations in subchondral bone. The endothelial isoform, endothelial cell nitric oxide synthase (eNOS), is constitutively expressed in bone, where it seems to play a key role in regulating osteoblast activity and bone formation. eNOS also mediates the effects of mechanical loading on the skeleton, where it acts along with prostaglandins to promote bone formation and suppress bone resorption.³²⁰ In contrast, such proinflammatory cytokines as IL-1 and TNF induce iNOS in bone cells, and NO derived from this pathway potentiates bone loss.²⁸⁷ Osteophyte formation and subchondral bone remodeling likely result from local production of anabolic growth factors such as insulin-like growth factor 1 (IGF-1) and mostly TGF- β , which is highly expressed in osteophytes of the femoral head in OA patients.^{321,322} Areas of increased radionuclide uptake (“hot spots”) on bone scintigraphy have also been reported to identify OA joints more likely to progress by radiographic criteria—and/or to require surgical intervention—over a 5-year period.²¹⁶

Alterations in Synovial Tissue

Synovial lining inflammation and synovial effusions have emerged as another key feature of OA pathophysiology. OA has traditionally been classified as a noninflammatory arthritis, largely because the synovial fluid leukocyte count in OA is typically fewer than 2000 cells/mm³. Such parameters can be misleading because low-grade inflammatory processes nevertheless occur in osteoarthritic synovial tissues and contribute to disease pathogenesis, and some degree of synovitis has been observed even in early OA.

This localized synovitis may be subclinical because arthroscopic studies suggest that localized proliferative and inflammatory changes of the synovium occur in up to 50% of OA patients, and the activated synovium may produce proteases and cytokines that accelerate damage to the adjacent cartilage.³²³ More recently, musculoskeletal ultrasound has provided a reliable noninvasive method to detect both synovial hypertrophy and even small effusions in OA patients, using both grayscale and power Doppler methods.³²⁴

Many of the clinical symptoms and signs seen in OA joints (e.g., joint swelling and effusion, stiffness, occasionally redness) reflect synovial inflammation. Synovial histologic changes include synovial hypertrophy and hyperplasia with an increased number of lining cells, often accompanied by infiltration of the sublining tissue with scattered foci of lymphocytes. In contrast to rheumatoid arthritis (RA), synovial inflammation in OA is mostly confined to areas adjacent to pathologically damaged cartilage and bone. This activated synovium can release proteinases and cytokines that may accelerate destruction of nearby cartilage.³²² Although synovial macrophages and macrophage-produced mediators result in key inflammatory cascades and cartilage destruction in both OA and RA, it appears there may be differences between the diseases in levels of the cytokines and how they mediate destruction of the cartilage.³²⁵

As described earlier, the metalloproteinases that degrade cartilage are produced not only by the cartilage itself but also by the synovium. Although cartilage destruction might be directed by the chondrocytes, some degree of synovitis exists in patients even with mild OA. A comprehensive analysis by Davidson and colleagues reported several proinflammatory genes significantly elevated in the synovium that had not previously been reported.¹⁴³ Cartilage breakdown products, derived from the articular surface as a result of mechanical or enzymatic destruction of the cartilage, can provoke the release of collagenase and other hydrolytic enzymes from synovial cells and macrophages (Figure 98-5).^{326,327} Cartilage breakdown products are also believed to result in mononuclear cell infiltration and vascular hyperplasia in the synovial membrane in OA.³²⁸⁻³³⁰

A consequence of the low-grade inflammatory processes is the induction of synovial IL-1 β and TNF, which are likely contributors to the degradative cascade.²⁸⁷ There are also reports of increased numbers of immune cells in synovial tissue including activated B cells and T lymphocytes, as well as evidence that OA patients express cellular immunity to the cartilage proteoglycan link protein and C1 domain.^{331,332} Histologic changes in OA synovium usually demonstrate mild or moderate synovitis characterized by an increase in the number of inflammatory mononuclear cells in the sublining tissue including activated B cells and T lymphocytes.³³³⁻³³⁸

A recent study of 10 patients with early OA (arthroscopic specimens) and 15 patients undergoing total knee arthroplasty revealed that synovial tissues from early OA had higher levels of IL-1 β and TNF and increased mononuclear cell infiltration compared with late OA.³³⁹

Along the lines of acute episodes of OA, the inflammation may result from crystal-induced synovitis (either calcium apatite or calcium pyrophosphate dihydrate). “Milwaukee shoulder syndrome” represents a rapidly destructive form of OA with evidence of inflammation in the synovial

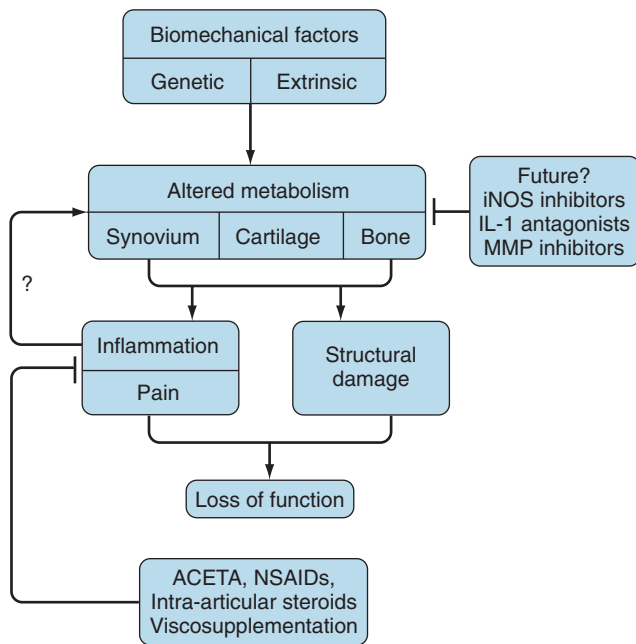

Figure 98-5 Multiple factors that predispose to, initiate, and perpetuate osteoarthritis. In the future, structure-modifying treatments will be targeted to the biochemical processes that promote disease progression. ACETA, acetaminophen; IL-1, interleukin-1; iNOS, inducible nitric oxide synthase; MMP, matrix metalloproteinase; NSAIDs, nonsteroidal anti-inflammatory drugs.

membrane but minimal synovial fluid leukocytosis. It is typically associated with rotator cuff degeneration, severe shoulder OA, and hydroxyapatite crystal deposition in the synovial membrane.³⁴⁰ The synovial fluid typically contains few cells and high levels of active collagenase. It is theorized that crystals released from the degenerating tendons trigger the release of collagenase from synovial mononuclear cells that leads to cartilage breakdown; cartilage breakdown products then further activate release of enzymes from the synovium. This inflammation is typically associated with increases in synovial IL-1 and TNF that further proteinate the degradative cascade.³⁴¹

Biomarkers of Osteoarthritis

The aims of biomarker research in OA are early detection before irreversible damage occurs, predicting OA progression, and monitoring response to therapeutic intervention.³⁴² The OA Biomarkers Network, funded by the National Institutes of Health, has established the “BIPED” biomarker classification with five separate categories of surrogate markers: burden of disease, investigative, prognostic, efficacy of intervention, and diagnostic.³²² Examples of burden of disease and prognosis for hip and knee OA include serum COMP, serum hyaluronic acid, and urinary CTXII.³⁴³ A recent survey revealed that this classification scheme was not adopted as often as anticipated, and therefore the authors undertook a systematic review of the primary OA biomarker literature to standardize the findings according to the BIPED classification.³⁴⁴

The major structural components in cartilage are type II collagen and aggrecan, which are relatively unique to cartilage. Additional constituents of articular cartilage include

the proteins COMP, cartilage intermediate layer protein (CILP), cartilage link protein, matrilin, minor collagens (types I, V, VI, IX, and XI), and hyaluronic acid. In healthy cartilage these molecules have a relatively slow turnover rate, whereas OA is characterized by enhanced synthesis and enzymatic degradation of most of these molecules. Therefore much focus in OA biomarkers has been on detecting markers of cartilage matrix synthesis and degradation.³⁴⁵ The biomarkers have been made more specific through the detection of “neo-epitopes,” or degraded cartilage matrix fragments generated by specific proteases enhanced in OA. The turnover of subchondral bone is also enhanced in OA, although biomarkers of bone turnover have proven less specific in identifying OA, perhaps because of the continuous bone remodeling in the skeleton as a whole. In addition to markers of matrix degradation and turnover, recent advances in the proteomics and microRNA fields have enabled detection of new OA biomarkers using unbiased screening of serum constituents in arthritic patients.¹²⁸ The slow progression of primary OA is causing researchers to refocus the search for OA biomarkers on more rapidly progressing secondary OA after acute injury.¹⁸¹

One study of 62 patients with knee OA compared MRI findings at baseline and 1 year, as well as levels of serum hyaluronic acid, osteocalcin, cartilage glycoprotein 39, COMP, and urine C-telopeptide of type II collagen. The researchers suggested that a single measurement of serum HA or short-term increases in urine CTXII would identify patients at greatest risk for progression of OA.³⁴⁶

Although OA is not considered an inflammatory disease in the traditional sense, it definitely involves inflammatory processes, and these hold promise as biomarkers for OA. For example, elevated levels of the inflammatory marker C-reactive protein (CRP) appear to be predictive of radiographic progression of long-term knee OA.²⁸⁷ In a study of 1025 women, higher levels of serum CRP were associated with a statistically significant increase in both prevalent and incident knee OA and greater knee OA severity; women with bilateral knee OA had higher CRP levels than those with unilateral knee OA. Compared with women who did not develop knee OA, those who did had a higher baseline CRP than at their index test 2.5 years earlier.³⁴⁷ In another study of women (age 44 to 67 years), CRP levels were statistically greater in 105 women with knee OA than in 740 women without OA. These results must be interpreted with caution because a recent study concluded that after adjustment of CRP levels to the patient’s body mass index, serum CRP levels were no longer correlated to OA.³⁴⁸ In summary, these and other studies report that inflammation markers such as CRP are modestly but significantly increased in early knee OA and can be predictive of OA that will progress over time.⁸⁹

Several studies have identified COMP levels as helpful assessors of the potential for, presence of, and progression of OA.^{349,350} This noncollagenous extracellular matrix protein, synthesized by both cartilage and synovium with TGF- β_1 stimulation,³⁵¹ is abundant in articular cartilage.³⁵²⁻³⁵⁵ Both the degradation and tissue distribution of COMP exhibit marked differences in normal and OA human knee articular cartilage. Synovial fluid COMP levels are higher in individuals with knee pain or injury,³⁵⁶ anterior cruciate ligament or meniscal injury,^{356,357} and OA^{356,358} than in

demographically matched healthy individuals. Similarly, serum levels of COMP are often higher in patients with more rapidly progressive joint damage,^{275,289,291} with some studies showing this specifically in hip OA^{293,359} and knee OA.²⁹⁰ Although COMP is one of the most useful serum markers for OA, the lack of specificity to OA and relatively high natural variations in serum COMP levels currently necessitate use of additional markers. The development of specific reagents to detect degradative products of COMP may increase its utility as an OA biomarker.³⁵⁰ As with other biomarkers based on anabolic and catabolic processes in cartilage, serum COMP levels indicate a specific stage of OA.

Hyaluronic acid (HA) is a marker of cartilage degradation that can be detected in synovial fluid and serum,³¹² even though the majority of circulating HA originates from extracartilaginous sources. HA levels reflect synovial activity, whereas proteoglycan levels reflect cartilage turnover.^{312,360} In addition, higher serum HA levels have been correlated with the number of joints involved and degree of clinical disability. These findings support the theory that serum HA levels reflect synovial hyperactivity. An animal model in which the anterior cruciate ligament was transected to induce OA also demonstrated a rise in serum HA level within 7 days after joint injury, a rise sustained at 13 weeks; the rise in synovial fluid HA levels correlated with serum levels.³⁶¹ Serum HA levels, which may also serve as a predictor of OA disease progression,^{293,362} correlated with radiographic evidence of disease progression over a 5-year time interval because patients whose disease progressed had higher levels than at the outset.³⁴³

SUMMARY

Osteoarthritis, although classically conceived of as a degenerative consequence of aging, is a disease with an increasingly well-characterized molecular pathophysiology. Biomechanical factors, particularly in the context of genetic predisposition, obesity, and malalignment, result in chemical alterations within the joint that promote cartilage degradation. Early, anabolic changes, characterized by proliferation of chondrocytes and increased matrix production, are followed by a predominantly catabolic state, characterized by decreased matrix synthesis, increased proteolytic degradation of matrix, and chondrocyte apoptosis. Many of the features of the chondrocyte in the catabolic state are related to the production of inflammatory mediators by synovium and chondrocytes that act locally to perpetuate cartilage degradation. Although current treatments improve the signs and symptoms of disease, further characterization of the altered metabolism in synovium, cartilage, and bone that promote disease progression should lead to future treatments that prevent structural damage in osteoarthritis.

KEY POINTS

Osteoarthritis is the most common form of arthritis, typically affecting the hands, hips, knees, spine, and feet.

Osteoarthritis can be defined radiographically, clinically, or symptomatically.

As more sensitive measures of damage from osteoarthritis become available, such as improved imaging and molecular biomarkers, definitions may change.

Pain and functional limitations contribute substantially to disability in osteoarthritis.

Mortality is increased among individuals with osteoarthritis compared with the general population.

Osteoarthritis (OA), the most common form of arthritis, is found worldwide and is strongly associated with aging. It affected 27 million adults in the United States in 2005.¹ OA of the knee and hip has significant functional impact due to effects on ambulation and mobility and is associated with considerable medical costs, accounting for 97% of the 455,000 total knee replacements and 83% of the 233,000 total hip replacements for arthritis in 2004.² Given the aging of our society and the obesity epidemic, the burden of OA can only be expected to increase over the next 20 years.³

OA affects all of the structures in and around a joint and should be considered a failure of the total joint. Historically, the emphasis in OA research has been on cartilage degeneration, but more recent work has expanded this view to an improved understanding of the role of subchondral bone, synovium, ligaments/tendons, meniscus, muscle, and nerve tissues in the disease process.^{4,5} The late- or end-stage joint, clinically recognizable as OA, likely represents a final common pathway of many different factors including genetics, environment, and biomechanical contributors.

EPIDEMIOLOGY OF OSTEOARTHRITIS

OA can be defined pathologically, radiographically, or clinically. The American College of Rheumatology (ACR) criteria for the classification of OA of the hand, hip, and knee are shown in Table 99-1.⁶⁻⁸ For the hand, only clinical criteria are used, with a sensitivity of 92% and specificity of 98%. For the hip, the sensitivity and specificity of the ACR criteria are estimated to be 91% and 89%, whereas for the knee they are 91% and 86%, respectively. Due to their high

Clinical Features of Osteoarthritis

AMANDA E. NELSON • JOANNE M. JORDAN

specificity, these criteria are most useful for differentiating OA from inflammatory arthropathy, but less so for differentiating early OA from healthy controls. Compared with radiographic definitions, the ACR criteria tend to underestimate prevalence of OA.^{9,10}

The presence of radiographic OA usually requires the presence of a definite osteophyte or joint space narrowing on plain radiographs, although magnetic resonance imaging (MRI)-based definitions are under development.¹¹ Clinical OA is usually defined by abnormalities on physical examination consistent with OA such as nodal changes in the hands, limited and painful internal rotation of the hip, or crepitus with knee movement. Symptomatic OA is usually defined as pain, aching, or stiffness in a joint with radiographic OA. Definitions can vary according to joint site, frequency or intensity of symptoms, and time span over which symptoms are assessed.

Prevalence of Radiographic Osteoarthritis

Because of the multiple different definitions of OA, prevalence estimates vary. The first National Health and Nutrition Examination Survey (NHANES I) found that 12% of the U.S. population had clinically defined OA in at least one joint. A few population-based studies have estimated the prevalence of radiographic OA at the knee, recently reviewed by Lawrence and colleagues.¹ Despite variations based on radiographic technique and participant age, these studies estimate that radiographic knee OA is present in 14% to 37% of U.S. adults and is more frequent in women.¹²⁻¹⁴ For radiographic hip OA, available estimates vary more widely, from less than 1% to 27%, depending on the population being studied.¹⁵ Radiographic hand OA is common, especially in older individuals, but it may not be symptomatic or functionally limiting. One large study found radiographic OA of at least one joint in 67% of women and 55% of men aged 55 years and older, with 28% having radiographic OA in at least two of three hand joint sites (distal or proximal interphalangeal or carpometacarpal).¹⁶ A recent review of radiographic findings in foot OA reported a prevalence of 12% to 35% for first metatarsophalangeal OA.¹⁷

Prevalence of Symptomatic Osteoarthritis

A summary of prevalence estimates for symptomatic OA (symptoms in the presence of radiographic OA) at the hands, knees, and hips is presented in Table 99-2.¹ On the basis of these findings, Lawrence and colleagues¹ estimated that more than 9 million U.S. adults are affected by symptomatic knee OA and more than 13 million have symptomatic hand OA.

Table 99-1 American College of Rheumatology Radiologic and Clinical Criteria for Osteoarthritis

Hand⁸
1. Hand pain, aching, or stiffness on most days of prior mo
2. Hard tissue enlargement of ≥ 2 of 10 selected joints*
3. Fewer than 3 swollen MCP joints
4. Hard tissue enlargement of ≥ 2 DIP joints
5. Deformity of ≥ 2 of 10 selected joints*
Diagnosis requires items 1-3 and either 4 or 5
*10 selected joints: DIP 2-3, PIP 2-3, and CMC 1 bilaterally
Knee: Clinical⁶
1. Knee pain for most days of prior mo
2. Crepitus with active joint motion
3. Morning stiffness lasting ≤ 30 min
4. Bony enlargement of the knee on examination
5. Age ≥ 38 yr
Diagnosis requires 1 + 2 + 4, or 1 + 2 + 3 + 5, or 1 + 4 + 5
Knee: Clinical and Radiographic
1. Knee pain for most days of prior mo
2. Osteophytes at joint margins
3. Synovial fluid typical of osteoarthritis
4. Age ≥ 40 yr
5. Morning stiffness lasting ≤ 30 min
6. Crepitus with active joint motion
Diagnosis requires: 1 + 2, or 1 + 3 + 5 + 6, or 1 + 4 + 5 + 6
Hip: Clinical and Radiographic⁷
1. Hip pain for most days of the prior mo
2. ESR ≤ 20 mm/hr
3. Radiographic femoral and/or acetabular osteophytes
4. Radiographic hip joint space narrowing
Diagnosis requires: 1 + 2 + 3, or 1 + 2 + 4, or 1 + 3 + 4

Primary and Secondary Osteoarthritis

Historically, osteoarthritis was considered to be “primary” in the absence of an injury history or other joint disease and “secondary” if a predisposing disorder was present (Table 99-3). However, as more and more local risk factors for OA

Table 99-2 Prevalence of Symptomatic Osteoarthritis (OA)

Modified from Altman R, Asch E, Bloch D, et al: Development of criteria for the classification and reporting of osteoarthritis. Classification of osteoarthritis of the knee. Diagnostic and Therapeutic Criteria Committee of the American Rheumatism Association, *Arthritis Rheum* 29(8):1039–1049, 1986.

have been identified (such as femoroacetabular impingement at the hip and malalignment at the knee) and a broader range of associated factors have been discovered (genetic, biomechanical, and environmental factors), the division between primary and secondary is less clear. Many individuals who develop secondary OA are likely predisposed to the condition with or without the identified inciting event; other individuals who have a disorder that is linked to secondary OA may not develop clinical OA. It may be most useful to think of OA as a common pathway through which an individual's genetics, history of injury or other joint damage, mechanical factors, and psychosocial milieu act on the joint, in some cases leading to an “end-stage” or “failed” joint.

CLINICAL FEATURES

General Symptoms and Signs

OA most commonly affects the knees, hands, feet, hips, and spine. These joints may be symptomatic or may be affected only on radiographs. Individuals with OA generally describe pain in the joint(s) that is worse with activity, with limited morning stiffness (<30 minutes), and pain and stiffness with rest. This stiffness after inactivity, or “gelling” phenomenon, is often a main complaint, although morning stiffness is generally less severe and of shorter duration than that seen

in systemic inflammatory arthropathies. Affected joints in OA often demonstrate bony enlargement and crepitus on examination, with concomitant reductions in range of motion. There may be soft tissue swelling or effusion, although these tend to be much less dramatic than in inflammatory arthritis. Pain complaints may be more or less than expected on the basis of structural damage.^{18,19} The effects of depression, disturbed sleep, and other psychosocial factors on the pain experience in OA are being increasingly recognized.²⁰⁻²³

Joint-Specific Symptoms and Signs: Knee

Knee OA is characterized by the insidious onset of pain with gelling and limited range of motion. Individuals with knee OA often describe pain and limitation with walking, transferring (as from seated to standing), and especially stair climbing. These complaints are often associated with a sensation of instability or “giving out” at the knee. A “locking” sensation at the knee can be a consequence of stiffness, loose bodies in the joint space, or meniscal lesions. Knees with OA often have demonstrable crepitus and bony enlargement. Pain may be elicited by palpation of the medial or lateral joint line, or both. Effusions, when present, are often cool and generally without redness. They can be associated with popliteal bursa enlargement (Baker’s cyst) when large. Associated pain over the anserine bursa, or even the greater trochanter, is often seen in knee OA and may be related to altered biomechanics.²⁴ Appreciation of such soft tissue symptoms is important because these may be amenable to corticosteroid injections with subsequent pain relief.

Malalignment, most often varus, is often seen in severe disease but can be present even in fairly mild/early disease. Clinically evident varus thrust may be a risk factor for progression.²⁵ Other signs of severe disease include flexion deformities or joint instability. Quadriceps weakness represents an early modifiable risk factor for knee OA progression, particularly in women,^{26,27} and in late stages of disease may be apparent as muscle atrophy.^{28,29} Alterations in proprioception and vibratory sense have been demonstrated in association with knee OA, although the relation of these factors to progression and pain is still unclear.³⁰⁻³²

Patellofemoral OA can strongly contribute to pain and disability at the knee but is often overlooked.³³ OA of the patellofemoral joint is characterized by pain with ascending or descending stairs and is often located anteriorly. It can be seen in isolation or in association with tibiofemoral OA. The relation between patellofemoral OA and commonly seen patellofemoral pain disorders in younger individuals remains to be elucidated.³⁴

Joint-Specific Symptoms and Signs: Hip

OA of the hip can present with groin pain, which is fairly specific³⁵ but may be described more vaguely as pain in the thigh, buttock, low back, or even in the ipsilateral knee. Therefore it is important to assess for other causes of pain in the “hip” including spinal pain (lumbar disk degeneration, spinal stenosis, facet joint OA, sacroiliac pain); trochanteric bursitis; altered gait due to knee pathology; meralgia paresthetica (lateral femoral cutaneous nerve

entrapment); thigh claudication from vascular causes; or even intrapelvic causes. It is also important to consider other causes of hip and groin pain such as occult femoral neck fracture or avascular necrosis. Persons affected by hip OA have limitations in walking, bending, and transferring, as well as stair climbing. Internal rotation of the affected hip is often limited and can be quite painful, even in early disease, often evident to the patient as difficulty putting on socks, tying shoes, or trimming toenails. Visible deformity, hip flexion contracture, or severe limitations of range of motion are indicators of more advanced disease, which may also be associated with shortening of the affected limb due to superior migration of the femoral head. In young individuals presenting with groin pain that is worsened by sitting, with pain and limitation when internally rotating and adducting the hip in the flexed position, femoroacetabular impingement is a consideration.³⁶

Joint-Specific Symptoms and Signs: Hand

The hands often provide the first clue to a diagnosis of OA. Evident bony enlargement of the distal interphalangeal (DIP) joints, called Heberden’s nodes, and proximal interphalangeal (PIP) joints, called Bouchard’s nodes, can be appreciated (Figure 99-1). These nodes may be acutely inflamed with warmth and tenderness or may be bland, hard enlargements and are often more marked in the dominant hand. Some patients, most commonly elderly women, have erosive osteoarthritis characterized by episodic inflammation, pain, and swelling. It remains a matter of debate whether this type of OA is part of the continuum or is in itself a separate disease entity.^{37,38} OA involvement of the first carpometacarpal (CMC) joint is particularly problematic and can lead to significant pain, limitations in functionality of the hand, and reduced grip strength.^{39,40} CMC squaring, representing deformity of the joint due to osteophyte formation and joint space narrowing, can be seen on examination. Bilateral involvement of multiple joints, both within (multiple PIPs) and across (both DIPs and PIPs) joint groups, is frequent. Metacarpophalangeal joints are affected more commonly than previously recognized,⁴¹⁻⁴³ although prominent involvement of these joints should prompt consideration of inflammatory arthropathies or secondary causes of OA such as hemochromatosis.⁴⁴ Again, soft tissue findings such as deQuervain’s tenosynovitis should be considered because they are associated with hand OA, can mimic or aggravate symptoms, and are amenable to conservative management.

Joint-Specific Symptoms and Signs: Spine

Facet joint arthritis is a common finding, is associated with back pain, and has many features in common with OA of other diarthrodial joints,⁴⁵ although few studies of this finding in association with OA at other sites have been reported.⁴⁶ Osteophytosis of the spine is nearly ubiquitous in older individuals, although it is often asymptomatic.⁴⁷ Lumbar disk degeneration (LDD), characterized by disk space narrowing, end-plate sclerosis, and herniation, is often seen in association with radiographic osteophytosis,⁴⁸ although the relationship between LDD and osteoarthritis of other joint sites remains controversial.⁴⁹ Clinical

Figure 99-1 Hands of a 79-year-old woman showing clinical (*top*) and radiographic (*bottom*) features of osteoarthritis (OA). This patient has Heberden's and Bouchard's nodes of multiple digits; radiographs show osteophytes, joint space narrowing, and cysts typical of OA, as well as "gull-wing" deformities at the third proximal interphalangeal joints suggestive of erosive OA.

symptoms in the cervical spine can include pain in the neck, often accompanied by radiation down the arms, sometimes with weakness or paresthesias due to compression of the cervical nerves secondary to osteophytic encroachment on intervertebral foramina or the spinal column. Large anterior cervical spine osteophytes can cause dysphagia due to compression of the esophagus.⁵⁰ Similarly, in the lumbosacral spine, osteophytes and disk space narrowing can lead to sciatic nerve impingement with pain, burning, numbness, and/or weakness down one or both legs. Diffuse idiopathic skeletal hyperostosis, or DISH, is characterized by exuberant osteophytosis and calcification of spinal ligaments and entheses, leading to an appearance likened to flowing candle wax.⁵¹ Individuals with DISH can be asymptomatic and identified only by radiographic appearance or can present in a fashion similar to OA or LDD.

Joint-Specific Symptoms and Signs: Shoulder

The shoulder is a common source of pain in patients with OA, although the symptoms are more often due to osteophytosis and narrowing of the acromioclavicular and/or

sternoclavicular joints than the glenohumeral joint itself. Other maladies common in older adults such as subacromial bursitis, rotator cuff pathology, and adhesive capsulitis should be assessed. Rotator cuff damage, in particular, can predispose to glenohumeral OA. Pathology at the cervical spine can present as pain in the shoulder region, so the shoulder evaluation should include an assessment of the cervical spine. Milwaukee shoulder syndrome is a destructive arthropathy of the glenohumeral joint associated with large effusions, which on aspiration often reveal high red blood cell content and basic calcium crystals.⁵²

Joint-Specific Symptoms and Signs: Other Joints

Osteoarthritis of the foot has been largely neglected in the literature to date. OA of the first metatarsophalangeal (MTP) joint is characterized by pain and hallux valgus (bunion) deformity and has radiographic features (joint space narrowing, osteophytosis) similar to OA at other joints. Loss of function at the first MTP joint due to ankylosis (hallux rigidus) can lead to altered gait. Other joints that can be affected by OA but are often not part of epidemiologic studies include the ankles (talonavicular and subtalar) and temporomandibular joint (TMJ). Elbow OA is rare and may be the result of trauma, vibration damage, or other entities such as pseudogout.

Polyarticular Osteoarthritis

It has been recognized for more than 100 years that OA can co-occur in multiple joint sites.⁵³ Although the term *generalized* OA (GOA) has been used to describe this disease entity, there is no universally understood or accepted definition of what constitutes GOA (Figure 99-2). Kellgren and Moore in 1952 provided the first clinical description of GOA, involving primarily Heberden's nodes and the CMC joints, with the spine, knees, hips, and feet involved in descending frequency.⁵⁴ Later studies have defined GOA as more than three or more than five joint sites affected,⁵⁵ affected joint counts,^{56,57} multiple hand joint involvement,⁵⁸ nodal hand OA with other joint involvement,⁴³ or summed scores of OA across multiple joints.^{59,60} It remains unclear which joints should be included in such definitions, particularly whether lumbar disk degeneration and hip OA are part of the same disease entity as other joints. Clinically, it is important to recognize and consider that a patient with OA in one joint is likely to have involvement at other sites and to assess the impact of that individual's overall OA burden on their functional status, rather than focusing on a single joint.

DIAGNOSTIC TESTING

Diagnostic Approach

The diagnosis of OA is a clinical one, and laboratory testing is rarely required. Similarly, if the diagnosis is clear on the basis of history and clinical findings, radiographs are often not required. The purpose of additional diagnostic testing in OA is primarily to exclude potentially treatable underlying conditions such as metabolic or inflammatory arthropathies.

Figure 99-2 Frequency of multiple joint involvement with radiographic osteoarthritis (OA) in the Genetics of Generalized Osteoarthritis Study. The frequencies of radiographic OA at various sites and sites in combination are shown for the United States in blue. For the United Kingdom they are shown in green for the 1963 participants meeting specified hand radiographic OA criteria. The groups represented are mutually exclusive. The frequency of spine OA (only assessed by U.S. sites) in combination with these phenotypes is indicated by the red bars. (Modified from Kraus VB, Jordan JM, Doherty M, et al: *The Genetics of Generalized Osteoarthritis (GOGO) study: study design and evaluation of osteoarthritis phenotypes*, *Osteoarthritis Cartil* 15:120–127, 2007.)

Laboratory Testing

There is rarely an indication for testing rheumatoid factor, antinuclear antibodies, or other serologic studies in the setting of clinically suspected OA, and such tests should be reserved for a patient in whom there are findings suggestive of an inflammatory arthropathy. Complete blood count, chemistry panel including glucose and creatinine, and liver function tests should be obtained before initiation of pharmacologic therapy for OA, especially in older individuals with comorbid medical conditions, due to an increased risk of adverse events in this population. In cases where there is prominent involvement of the metacarpophalangeal (MCP) joints, evaluation for hypothyroidism and hemochromatosis may be warranted.

Synovial Fluid

The synovial fluid in OA is typically normal or mildly inflammatory, appearing clear and colorless to slightly yellowish. The leukocyte cell count is typically less than or equal to 2000 cells/mm³ (<2 cells seen across 10 high-power fields).⁶¹ Fluid is often obtained in the course of a symptomatic joint injection, although diagnostic aspiration may be done in the setting of an effusion. Concomitant calcium pyrophosphate crystal disease can be identified, although other calcium crystals, or hydroxyapatite, are not seen on routine preparations.

Molecular Biomarkers

Quantitative determination of the products of cartilage and bone metabolism has provided several putative biomarkers of OA pathophysiology. As an example, one such biomarker, urinary C-telopeptide fragments of type II collagen (u-CTXII), is associated with the occurrence and progression of radiographic OA, independent of other risk factors.^{46,62} Such biomarkers, obtained from serum, urine, or synovial fluid, may eventually provide a method for early diagnosis and monitoring of treatment effect, although they are currently used primarily in research. Interested readers are referred to a comprehensive review of biomarkers by van Spil and colleagues.⁶³

Imaging: Conventional Radiography, General Considerations

Conventional radiography is widely available and relatively inexpensive, making this modality useful to confirm the diagnosis and exclude others, primarily when there is clinical uncertainty regarding the diagnosis, when the joint involved is atypical, or when evidence exists to suggest other diagnoses such as inflammatory arthritis, fractures, Paget's disease, osteonecrosis, infection, or malignancy. Radiographs of joints affected by osteoarthritis typically show osteophytes, joint space narrowing, sclerosis, and cysts of subchondral bone.⁶⁴ The Kellgren-Lawrence (KL) grading system remains the most commonly used for research purposes.⁶⁵ KL grades range from 0 (no osteophytes or joint space narrowing) to 4 (severe joint space narrowing with subchondral sclerosis); a grade of 2 is generally considered diagnostic of osteoarthritis. The KL system relies on osteophytes and may underestimate OA in individuals with a more atrophic subtype (where joint space narrowing is more severe than osteophytosis, particularly at the hip). Other grading systems, such as the Osteoarthritis Research Society International (OARSI) grading system, view osteophytes and joint space narrowing separately and assign separate scores (Figure 99-3).⁶⁶ The choice of grading system depends on the goal of the study and the joint site of interest.

Imaging: Conventional Radiography, Specific Joint Issues

Imaging of the knees should be bilateral and in weight bearing, and for clinical purposes it should generally be anteroposterior (AP). Lateral, posteroanterior, or sunrise views may be necessary in some circumstances. Alignment, although best determined from full-limb views, can be estimated from routine knee films.⁶⁷ An AP pelvis view should be obtained to assess hip OA and can be supine or weight bearing. Additional views such as frog-leg or lateral images may be indicated for specific hip pathology or to assess for femoroacetabular impingement or congenital abnormalities. An atrophic subtype of hip OA, characterized by joint space narrowing with either mild or absent osteophytosis, has been described,⁶⁸ and alternative radiographic definitions for hip OA (other than KL grading) have been proposed and used in research to address this issue.^{10,69} For hand OA, a posteroanterior view of both hands including the

Figure 99-3 Examples of semiquantitative radiographic assessment with use of the Kellgren-Lawrence and Osteoarthritis Research Society International (OARSI) grading schemes. **A**, Kellgren-Lawrence grade 3. No lateral femoral and tibial osteophytes are seen (OARSI grade 0). A medial femoral osteophyte: OARSI grade 1 (white arrow); a medial tibial osteophyte: OARSI grade 2 (white arrowhead); lateral tibiofemoral joint-space width: OARSI grade 0; and medial tibiofemoral joint-space narrowing: OARSI grade 2 (black arrows) are depicted. **B**, Kellgren-Lawrence grade 2. A lateral femoral osteophyte: OARSI grade 2 (white arrow); a lateral tibial osteophyte: OARSI grade 2 (white arrowheads); a medial femoral osteophyte: OARSI grade 3 (short black arrows); a medial tibial osteophyte: OARSI grade 2 (black arrowhead); a normal lateral tibiofemoral joint-space width: OARSI grade 0; and medial tibiofemoral joint-space width: OARSI grade 1 (long black arrows) are shown. (From Guermazi A, Hunter DJ, Roemer FW: Plain radiography and magnetic resonance imaging diagnostics in osteoarthritis: validated staging and scoring, *J Bone Joint Surg Am* 91(Suppl 1):54–62, 2009.)

wrists will reveal the characteristic features of OA. If there is an erosive component to hand OA, radiographs may demonstrate central erosions and “gull-wing” deformities of the interphalangeal joints. Marked destructive changes at the DIP joints may indicate another inflammatory disorder such as psoriatic arthritis or, rarely, multicentric reticulohistiocytosis. Prominent involvement of the MCP joints may indicate a metabolic process such as hemochromatosis or calcium pyrophosphate deposition disease. Conventional radiography of the lateral lumbar spine can show facet OA, disk space narrowing, and osteophytosis.

Imaging: Advanced Modalities

Other imaging modalities, such as MRI, can be useful to exclude avascular necrosis, stress fractures, other occult fractures, infectious processes, or inflammatory arthropathy. MRI is increasingly used in OA research as a means to obtain information about structural changes earlier in the disease process, before findings are apparent on conventional radiographs. Bone marrow lesions identified on knee MRI, for example, have been shown to correlate with pain, meniscal lesions, bone attrition, and progressive cartilage damage (Figure 99-4).^{5,70-72} However, due to a lack of effective treatment options in OA; growing evidence that surgical interventions such as knee arthroscopy, which are often

a response to findings on MRI, are overused and generally ineffective⁷³; and the cost associated with these studies, they are generally not indicated in routine clinical practice at present. Ultrasound is gaining in popularity and may have a role at the bedside in detecting small effusions, identifying early cartilage changes, differentiating inflammatory from noninflammatory arthropathies, and as a therapeutic adjunct to allow more accurate aspirations and placement of intra-articular injections.⁷⁴⁻⁷⁷

OUTCOME

Performance Measures and Functional Assessment

Although not routinely used in clinical practice, there are several validated tools for assessing functional status in OA that are widely used in research settings. Results on standardized performance-based tests such as determination of walking speed and time to stand from a chair five times unassisted have been shown to correlate with the severity and number of affected joints in OA.^{78,79} Questionnaire-based measures such as the Stanford Health Assessment Questionnaire (HAQ) disability index (for overall function), Western Ontario and McMaster Universities Arthritis Index (WOMAC, focused on lower extremity joints,

Figure 99-4 Subchondral bone marrow lesion (BML) in osteoarthritis. **A**, Sagittal proton density fat suppressed (FS) image. Tibial BML is depicted as diffuse hyperintensity (arrowheads). **B**, T1-weighted FS image after intravenous gadolinium diethylene triamine penta-acetic acid administration shows BML with similar extent (arrows). (From Roemer FW, Frobell R, Hunter DJ, et al: MRI-detected subchondral bone marrow signal alterations of the knee joint: terminology, imaging appearance, relevance and radiological differential diagnosis, *Osteoarthritis Cartil* 17:1115–1131, 2009.)

Table 99-4), and Australian/Canadian Hand Osteoarthritis Index (AUSCAN, for hand-specific function), are often used to assess the functional impact of OA on affected individuals for research purposes.⁸⁰⁻⁸²

Time to Total Joint Replacement

Total joint replacement is a “hard” endpoint in OA, but its use as an outcome measure is hampered by a variety of factors affecting an individual patient’s decision to undergo this procedure including insurance coverage, procedure availability, comorbid conditions, ability to rehabilitate the joint, and patient preference.^{83,84} Therefore efforts are ongoing to identify a composite index that would define the “need for total joint replacement,” which could be used as an outcome measure.^{85,86}

Mortality in Osteoarthritis

Moderate evidence indicates increased mortality in individuals with OA compared with the general population.⁸⁷ The apparent modestly increased mortality risk, determined through a review of nine studies, appears to be primarily due to cardiovascular and gastrointestinal causes. One study showed an increased mortality risk with increasing numbers of joint groups affected by OA, as well as reduced survival in individuals with hand, bilateral knee, or cervical spine involvement, but not in those with OA of the hip, foot, or lumbar spine.⁸⁸ Contributors to increased mortality risk include a combination of reduced physical activity among individuals with OA, comorbid conditions, and/or adverse medication effects such as are seen with acetaminophen and nonsteroidal anti-inflammatory drugs.⁸⁷

Sitting?
Getting on or off the toilet?
Heavy domestic duties?
Light domestic duties?

Modified from Bellamy N, Buchanan WW, Goldsmith CH, et al: Validation study of WOMAC: a health status instrument for measuring clinically important patient relevant outcomes to antirheumatic drug therapy in patients with osteoarthritis of the hip or knee, *J Rheumatol* 15(12):1833–1840, 1988.

SUMMARY

OA is a highly prevalent and debilitating condition, with increasing prevalence along with the aging of our society and the ongoing obesity epidemic. OA is readily recognized on clinical grounds, although further diagnostic testing and imaging are indicated in some cases to assess for potentially treatable underlying conditions. Pain is the most common reason for a patient with OA to seek medical advice, and examination often reveals loss of function. Assessment of the patient's pain symptoms and functional limitations, in the framework of that individual's goals, is necessary to formulate an appropriate plan of care in the absence of disease-modifying medications. Current research in OA, in addition to ongoing efforts in both pharmacologic and non-pharmacologic therapeutic development, is focused on optimizing incident case and progressor definitions and understanding the whole-body burden of OA.

Treatment of Osteoarthritis

CARLOS J. LOZADA

KEY POINTS

Osteoarthritis (OA) is the most common form of arthritis.

Pain is the most common symptom in patients with OA.

The management plan should be individualized, accounting for factors such as sources of pain and extent of accompanying inflammatory features.

Nonpharmacologic interventions such as weight loss and exercise should be an integral part of the management plan for OA.

Currently available pharmacologic interventions are directed at symptomatic relief.

Investigation continues into potential disease-modifying interventions in OA.

Osteoarthritis (OA) is the most common form of arthritis. It is often referred to by other names such as *arthrosis*, *osteoarthrosis*, or simply *arthritis*. Because its incidence increases with age, OA is becoming an increasingly important health issue with the “graying” of the world’s population.

OA can be defined radiographically or clinically. The most useful definition, however, includes symptoms and radiographic changes. If a purely radiographic definition is used, it can be demonstrated that almost all individuals older than 75 years have OA.¹ Although the epidemiology of OA is well covered in Chapter 99, it has been estimated that between 10% and 30% of those affected with OA are significantly disabled, making OA the leading cause of chronic disability in the United States.² This leads to substantial direct and indirect costs.

Traditional treatment paradigms for OA have conceded the inexorable progression of the disease and concentrated on pain management.³ A simplistic but potentially useful algorithm is provided in Figure 100-1. As the population ages, there will be increasing societal pressure on physicians, particularly rheumatologists, to improve the available treatments for OA.⁴⁻⁶ Researchers have turned to the investigation of agents that might delay the progression of OA. Particular investigational agents have included collagenase inhibitors, nutritional supplements, and polysaccharides, although many novel molecular entities are now under exploration.⁷

PATIENT ASSESSMENT

Appropriate management of OA begins with an accurate diagnosis. As with most rheumatic illnesses, obtaining a good history is of paramount importance. Symptoms should

be carefully described, particularly pain. Duration, location, and any alleviating or exacerbating factors should be ascertained. Distinct features such as stiffness or gelling and the description of events such as “locking” or “giving way” of a joint can help direct the physical examination.

The physical examination seeks to confirm the diagnostic suspicion and establish the causes of symptoms. Laboratory evaluations are not helpful in establishing the diagnosis of OA but can help in excluding alternative diagnoses. They are also useful in determining which therapeutic approaches are appropriate for a particular patient because conditions such as renal insufficiency or anemia can be identified.

Radiographs are not necessary for diagnosis in the majority of patients but can identify coexistent conditions such as chondrocalcinosis that may require further workup or modification of the therapeutic plan.

SOURCE OF PAIN

The main symptom in OA is pain. It has many potential sources in and around the joint. These include focal synovitis, synovial effusions, subchondral bone pain receptors, and periarticular tendons and bursae. Factors complicating the determination of the source of pain may include varus or valgus deformity, weight issues, and the emotional impact of chronic pain. Once the source or sources of pain are accurately identified, a treatment plan can be formulated.

MANAGEMENT

The management of OA can be divided into nonpharmacologic interventions (Table 100-1), pharmacologic interventions, and surgical options. Pharmacologic interventions can be further subdivided into symptomatic therapy and potential structure- or disease-modifying therapy.

Nonpharmacologic Interventions

Psychosocial Interventions

As in other types of arthritis, patient education is an important first step in OA therapy. The patient should be an integral part of the decision-making team. To do this effectively, the patient should understand the nature of OA including its natural history and treatment options. It is often reassuring for the patient to realize that OA is a common, slowly progressive ailment and is not typically as disabling or deforming as the inflammatory arthritides. A significant number of patients have already tried nonprescription medications or nutraceutical remedies before

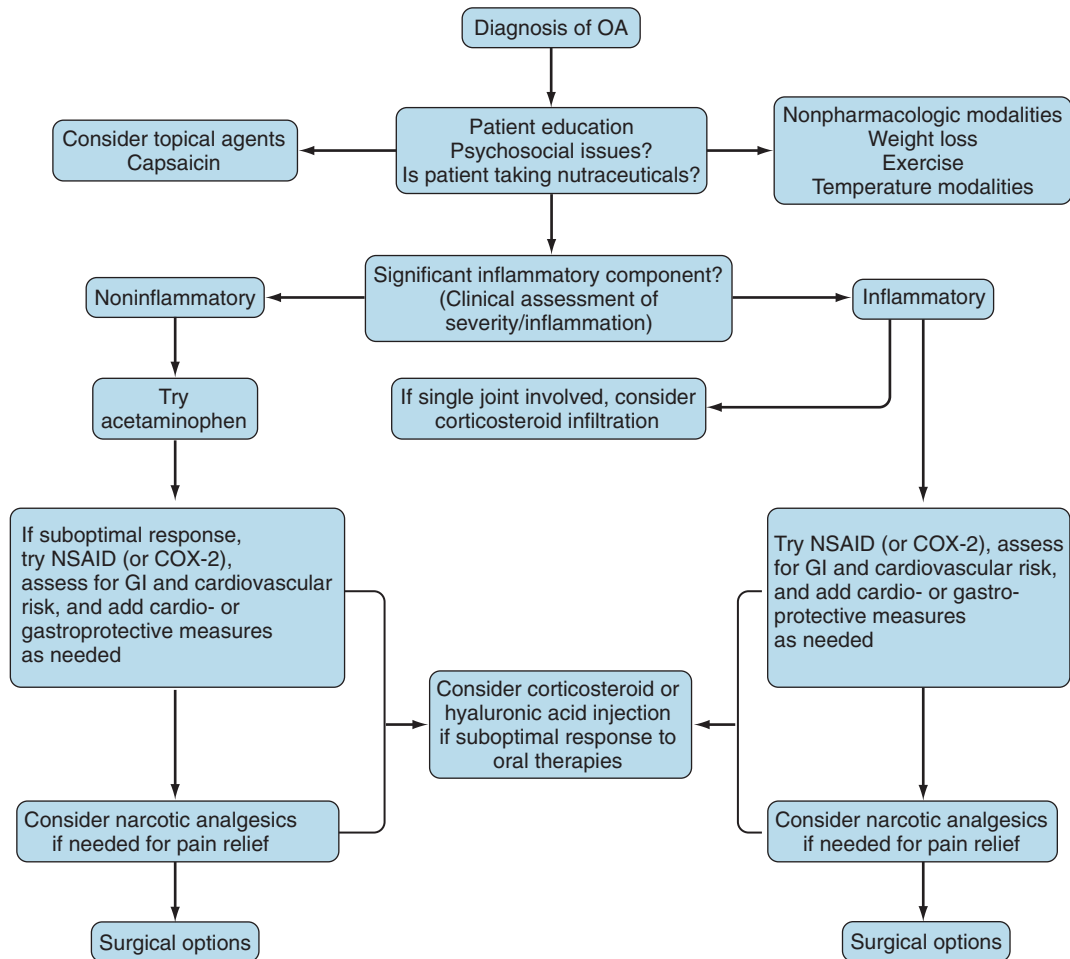

Figure 100-1 Algorithm for the management of osteoarthritis (OA). COX, cyclooxygenase; GI, gastrointestinal; NSAID, nonsteroidal anti-inflammatory drug.

seeing a physician and will want to discuss these options. Physicians should emphasize that treatment includes nonpharmacologic and pharmacologic interventions. Organizations such as the Arthritis Foundation can be valuable sources of information geared toward patients and can provide helpful reading materials.

Some patients may develop significant emotional disturbances related to the pain and changes in normal daily

activities that can stem from OA. These may include mood disorders such as depression or sleep disorders. Worsened measures of mental health have been associated with increased OA pain and risk of flares.⁸ Suspicion of either condition should lead to an evaluation by a psychiatrist or a primary physician who regularly manages these types of disorders.

Weight Loss

Obesity is an important risk factor in the development of OA of the knee.^{9,10} Further, higher body mass index (BMI) has been associated with an increased risk of progression of OA of the knee.¹¹ This can be compounded by malalignment—namely, varus and valgus deformities that modulate the effect of weight on knee OA.¹² In one study, BMI was associated with OA severity in those with varus deformity but not in those with valgus.

Regimens of weight loss and exercise have been associated with improvement in pain and disability in OA of the knee.¹³ Weight loss alone has been associated with a decrease in the odds of developing symptomatic knee OA.¹⁴ One study suggested that a reduction in the percentage of body fat, rather than weight, may be significant in reducing pain from OA of the knee.¹⁵ The symptom-relieving effects of weight loss have been shown to last as long as 1 year.¹⁶ The

combination of weight loss and exercise can be superior to either intervention alone.¹⁷

Temperature Modalities

Topical applications of heat or cold can be a helpful adjunct to the therapeutic plan. These are more effectively used in superficial joints such as the knees than in deep ones such as the hip. An acute injury such as a sprained ankle calls for cold applications for the first 2 to 3 days.¹⁸ In a setting of chronic pain, most patients prefer warm applications, although if superior pain relief is obtained from cold applications, these can be continued.

Warm applications can be in the form of warm soaks or heating pads. Individual sessions should not exceed a temperature of 45° C or last more than approximately 30 minutes.¹⁹ The application of warmth should be avoided over certain areas such as close to the testicles and in patients with poor vascular supply, neuropathy, or cancer. Benefits of warm applications include decreased pain and stiffness, along with relief of muscle spasm and prevention of contractures.

Exercise

Periarticular structures, particularly muscles, influence the expression of OA. This is likely due to their role in providing stability to the joints and in dampening some of the forces acting across joints. Quadriceps muscle weakness has been postulated as a risk factor for OA of the knee.²⁰ Quadriceps strengthening exercises have been advanced as fundamental to the management of conditions such as chondromalacia patellae.²¹

Both the dynamic and isometric exercise arms of a 16-week study of patients with knee OA showed equivalent improvement in symptoms and physical functioning.²² Walking can be beneficial, and supervised fitness-walking regimens can improve function in those with OA of the knee.²¹ Home-based exercise interventions also significantly improve symptoms in those with knee OA.^{23,24} Finally, community-based aquatic exercise programs such as aquatic aerobics have merit.²⁵

Orthotics and Bracing

Orthotics—ranging from insoles to braces—can be effective in providing symptomatic relief and are probably underused by most physicians. Studies have demonstrated that lateral wedged insoles provide substantial relief to those with medial compartment knee OA, particularly those with varus deformity.²⁶ In some studies, those with milder symptoms obtained greater benefit.²⁷ Knee braces have been evaluated as well. Valgus bracing of patients with medial compartment OA can reduce pain and increase levels of activity.²⁸ In one study, medial taping of the patella reduced the pain of those with patellofemoral compartment OA by 25%.²⁹

Heel lifts have been tried in those with hip OA. In an uncontrolled study, most patients reported diminished symptoms. Time to improvement lengthened with the radiographic stage of OA.³⁰ For those with calcaneal spurs or foot joint OA in general, appropriate athletic-type

footwear is recommended. A good athletic shoe should provide medial arch support and calcaneal cushioning, as well as good mediolateral stability.

Those with carpometacarpal joint arthritis should initially be offered conservative management including the use of splints. In one trial, 70% of patients treated with a 7-month intervention that included the use of splints were able to improve their symptoms considerably and avoid surgical intervention.³¹

Cane/Walking Aid

The appropriate use of a cane (walking stick) can be an important adjunct, particularly in OA of the hip. It has been estimated that a cane can provide up to a 40% reduction in hip contact forces during ambulation.³² The cane should be used in the hand contralateral to the affected hip or knee³³ and should be advanced with the affected limb while walking. The appropriate cane size is that which results in about a 20-degree flexion of the elbow during use.³⁴ A useful approximation is a cane that is equal to the distance from the floor to the patient's greater trochanter.

Modification in Activities of Daily Living

Physician advice and occupational therapy can provide useful insights into modifications of daily activities to reduce OA symptoms. These interventions can range from using an elevated toilet seat or shower bench in someone with lower extremity OA to using appliances designed to open jars in patients with hand OA. Assistance from occupational therapists can be valuable.

Other Interventions

Other modalities have been tried in OA. These are unconventional and include magnetic field application, acupuncture, and yoga-based regimens. These are not accepted as standard therapy for OA, but some deserve further study. A significant number of these interventions are being used by patients on their own and should be formally studied not only for evidence of any benefit but also to ensure that there are no harmful effects.

Studies of transcutaneous electrical nerve stimulation (TENS) have generally been small. A review of TENS studies in OA of the knee concluded that a trend toward symptom improvement existed, warranting larger, well-controlled studies.³⁵ In one randomized, controlled study, patients had initial symptom reduction, but at 1-year follow-up, only two patients continued to use the device.³⁶ TENS use for 3 weeks was compared with three weekly hyaluronic acid injections in 60 patients with OA of the knee. Pain relief was observed in both groups through the 6 months of follow-up. There was superior improvement in the Western Ontario McMaster Universities Osteoarthritis Index (WOMAC) physical function subscale score for the hyaluronic acid group.³⁷

Pulsed electromagnetic fields have been tested in double-blind, placebo-controlled trials. These fields are applied through the daily use of a brace-type device. In one study, a primary endpoint of pain reduction was not achieved.³⁸ Another study did not meet its primary endpoint but

reported an improvement in knee stiffness in subjects younger than 65 years, without an accompanying reduction in pain.³⁹

The use of static magnets in chronic knee pain has become popular with some patients. In one double-blind, randomized, placebo-controlled trial of 43 patients, the WOMAC pain and physical function subscales, along with a 50-foot walk, demonstrated a statistically significant benefit of static magnets at 2 weeks.⁴⁰ Another 29-patient double-blind, placebo-controlled trial in knee OA reported a benefit over placebo after 4 hours of use, but there were no significant differences between groups at 6 weeks of continued treatment.⁴¹ The potential mechanism for any effect remains unclear, and larger, longer-term studies are necessary before any clinical benefit can be postulated.

Acupuncture is being formally tested in a National Institutes of Health (NIH)–sponsored multicenter clinical trial. It has been difficult to develop appropriate controls to test acupuncture's clinical efficacy. Most recent studies have tried to employ “sham” methods in the control arm such as the use of blunted, telescopic needles.⁴² Early clinical trials^{43,44} and one literature review⁴⁵ concluded that acupuncture shows promise in the treatment of knee pain from OA. A double-blind, randomized, placebo-controlled trial of acupuncture as adjunctive therapy in OA of the knee enrolled 570 patients in two outpatient clinics. Reduction in knee pain in the true acupuncture group was superior to that in the sham acupuncture group at 26 weeks by WOMAC function score, WOMAC pain score, and patient global assessment. Twenty-five percent of the patients in each of the acupuncture groups were unavailable for analysis at 26 weeks, however.⁴⁶

The most recent and largest randomized, double-blind, placebo-controlled trial of acupuncture in knee OA showed a benefit of both sham and “traditional” methods of acupuncture over physiotherapy and as-needed nonsteroidal anti-inflammatory drugs (NSAIDs); however, there were no significant differences between the sham and “traditional” arms of the studies in terms of OA symptom relief. The beneficial pain-relieving effect seen in slightly more than half the patients in each of these arms appeared to be secondary to the use of the needles themselves rather than the specific locations where they were placed.

Spa therapy also has advocates. It has been touted for low back pain and for lower extremity OA.⁴⁷ However, randomized, controlled studies are lacking.⁴⁸ Yoga has also shown some symptomatic benefit in OA of the hands on the basis of limited testing.⁴⁹

Pharmacologic Interventions

Topical Agents

Topical agents for the management of OA are available without a prescription in the United States (Table 100-2). The two most widely used types are preparations containing capsaicin and those containing topical NSAIDs.

Capsaicin is a pungent ingredient found in red peppers (such as hot chili peppers). The mechanism of action is thought to be through selective stimulation of unmyelinated type C afferent neurons, causing the release of substance P. This release reversibly depletes the stores of

substance P, a neurotransmitter of peripheral pain sensations.⁵⁰ Capsaicin preparations are available in concentrations of 0.025% or 0.075% in either ointment or, more recently, “roll-on” form, and they can be applied up to four times daily. They have been tested in controlled, double-blind studies in OA of the hands and knees.^{51,52} Patient response is quite variable, with some obtaining significant pain relief and others not being able to tolerate the burning or stinging sensation produced by its application. Usually, the counterirritant sensation decreases gradually with repeated use, but pain relief remains. Although safe overall, capsaicin products can be irritating if they come in contact with mucosal surfaces, particularly the eyes. Patients should wear disposable gloves, if possible, when applying the agents. There may be some reddening of the skin where the compound is applied.

Topical NSAID preparations are popular worldwide for the treatments of OA.^{53,54} Safety concerns about traditional oral NSAIDs were the driving force in the use of these topical agents,⁵⁵ although questions remain as to their absorption and the degree of relief obtained. Results of placebo-controlled trials in OA of the knee have been conflicting. Some demonstrated symptomatic relief with topical application of gels containing NSAIDs such as diclofenac,^{56,57} whereas others showed only trends favoring the NSAID or no difference at all. In one trial, diclofenac gel was compared with placebo in 238 patients with OA of the knee over 3 weeks. The primary outcome was average pain with movement on days 1 to 14. The group on diclofenac gel had statistically superior improvement in this variable compared with those on placebo. WOMAC scores for function, pain, and disability were also significantly superior to placebo at weeks 2 and 3.⁵⁸ Transdermal diclofenac patches are also available and can be applied twice daily to painful articular locations. Patients were also randomized to receive eltenac or placebo gel over 4 weeks. Eltenac is a nonselective NSAID that is structurally similar to diclofenac. The primary endpoint was global pain on a visual analogue scale (VAS). At 4 weeks, there was a trend, but no statistical difference, favoring the eltenac gel. Two patients in the active treatment group and two in the placebo group had local itching, reddening, or both in the application area. There are also menthol- and salicylate-based over-the-counter topical preparations, but there are

no published trials supporting their use in OA. Finally, lidocaine has gained popularity as a topical agent for musculoskeletal pain. Transdermal lidocaine 5% patches are available for management of pain and can be applied to up to three articular and periarticular locations at a time as an analgesic agent for 12-hour periods.

Systemic Agents

Non-narcotic Analgesics. Acetaminophen (paracetamol) has often been touted as the initial systemic intervention for the management of OA. This is mainly due to its favorable side effect profile but also to a perception of its equivalent efficacy to NSAIDs. This perception derives from studies of OA in which patients were not stratified in terms of degree of symptoms. In one study, acetaminophen 4 g/day was equivalent to ibuprofen 1200 or 2400 mg/day, with the notable exception of pain at rest.⁵⁹ A meta-analysis of 10 randomized, controlled trials concluded that acetaminophen is effective in the relief of pain associated with OA. However, the effect was small, and there was no improvement in overall WOMAC score. This suggests that acetaminophen may be effective for the relief of pain and should not be expected to have a strong effect on stiffness or function.⁶⁰ More recently, it has been noted that NSAIDs may have superior efficacy in patients with more symptomatic or inflammatory presentations because acetaminophen has no anti-inflammatory effects at approved doses.⁶¹ A recent database review concluded that the available evidence suggests that NSAIDs have superior efficacy in symptomatic relief in those with hip or knee OA and also in those with moderate to severe levels of pain from OA.⁶² Particular concerns in patients taking acetaminophen include the concomitant use of alcohol or over-the-counter products containing acetaminophen. Either of these situations can lead to the possibility of hepatic toxicity through toxic metabolites.

Nonsteroidal Anti-inflammatory Drugs. NSAIDs are the most commonly prescribed medications for the treatment of OA. Nonselective NSAIDs work through nonspecific inhibition of cyclooxygenase isoforms 1 and 2 (COX-1 and COX-2). COX-1 is constitutively expressed in renal and gastrointestinal (GI) tissues, among others. COX-2 is inducible in inflammatory responses. The major side effects of NSAIDs are GI toxicities (gastritis, peptic ulcer disease) and renal toxicities (interstitial nephritis, prostaglandin inhibition–related renal insufficiency). Because GI tissues have a higher expression of COX-1, a selective COX-2 inhibitor might spare patients the GI side effects. Unfortunately, COX-2 is expressed in renal tissue, and COX-2–specific drugs such as traditional NSAIDs have potential adverse renal effects. This is especially true in those with baseline renal insufficiency. Concerns about cardiovascular risks led to the voluntary withdrawal of rofecoxib from the market in the United States. There have also been concerns about celecoxib at a dose of 200 mg twice daily, owing to an increased relative risk for myocardial infarction in an adenomatous polyp trial⁶³; this, however, has not been confirmed in six observational studies.⁶⁴ All NSAIDs and COX-2–specific agents have received “black box” warnings in their package inserts addressing cardiovascular risk. Alternative mechanisms of action of NSAIDs such as

interference with receptors in the cell membrane phospholipid bilayers have been proposed.⁶⁵

Nonselective NSAIDs are widely used for the management of OA. They include ibuprofen, naproxen, and diclofenac. NSAIDs are usually analgesic at lower doses but have both analgesic and anti-inflammatory effects at their higher recommended doses. They are prescribed either in fixed doses or “as needed” and are quite effective as symptom modifiers; however, they have no structure- or disease-modifying effects. NSAIDs should be used in the smallest dose that provides satisfactory symptom relief because GI toxicity has been linked to dosage. Adverse GI events have also been linked to patient age, previous history of peptic ulcers or bleeding, and the presence of comorbid conditions such as heart disease.

To reduce the potential for adverse GI events, misoprostol can be added to the therapeutic regimen. It is a prostaglandin E₂ analogue that has been shown to reduce the GI side effects of NSAIDs when used at 200 µg three times a day.⁶⁶ Diarrhea is a potential side effect. The use of a concomitant proton pump inhibitor may reduce upper GI endoscopic ulceration rates from NSAIDs, although no study has attempted to show a decrease in events such as symptomatic ulcers or bleeds.⁶⁷ Over-the-counter doses of H₂ blockers and antacids have not been shown to reduce either endoscopic or serious clinical GI events. COX-2–specific inhibitors are the latest drugs used in an attempt to reduce the GI adverse event profile of OA therapy.

COX-2–specific inhibitors are highly selective for COX-2 *in vitro*. Currently, only one such agent is available in the United States, celecoxib. Others such as etoricoxib are available elsewhere. These agents have been shown to reduce the rate of endoscopic ulceration by more than 50% when compared with nonselective NSAIDs. Celecoxib significantly reduces the rates of symptomatic ulcers, bleeds, perforations, and obstructions in patients not concurrently on aspirin.^{68,69} It remains unclear how substantial the gastrointestinal benefits of these compounds are to patients taking aspirin. Because COX-2–specific agents can inhibit endothelial prostacyclin but do not affect platelet thromboxane, cardiovascular safety remains an area of investigation.^{70,71}

Combination COX-lipoxygenase inhibitors are still investigational. It remains to be seen how these will compare with traditional NSAIDs and with COX-2 inhibitors in terms of both safety and efficacy.⁷² Animal studies have hinted at the possibility of a structure- and disease-modifying effect.⁷³

Narcotic Analgesics. Although several options exist for the management of pain in OA, some patients obtain suboptimal pain relief. If a patient has failed to respond to other nonpharmacologic and pharmacologic modalities and has no additional identifiable causes of pain (such as fibromyalgia), a narcotic analgesic should be considered.

The pain of OA is generally responsive to narcotic analgesics. Because of concerns about potential addiction, appropriate patient selection is important. Narcotic analgesics such as codeine and propoxyphene have been used effectively in patients with OA, especially in combination with non-narcotic analgesics (e.g., acetaminophen). Potential side effects include nausea, constipation, and somnolence.

Tramadol is an oral medication with mild suppressive effects on the mu opioid receptor. It also inhibits the uptake of norepinephrine and serotonin⁷⁴ and is not thought to have significant addictive tendencies.⁷⁵ It is available alone or in combination with acetaminophen and is not a controlled-schedule medication in the United States.⁷⁶ Tramadol has been used for the symptomatic relief of OA.⁷⁷ Seizures and allergic reactions are potential side effects.⁷⁸ A warning of increased risk of suicide in certain patients, similar to that on antidepressants, has been added to the label. The incidence of nausea can be reduced by slowly escalating the dose until the desired pain relief is achieved.

One study compared tramadol and acetaminophen with the combination of codeine and acetaminophen.⁷⁹ Patients with OA or chronic low back pain were randomized to receive tramadol and acetaminophen (37.5 mg and 325 mg, respectively) or codeine and acetaminophen (30 mg and 300 mg, respectively) for 4 weeks. Pain relief and changes in pain intensity were equivalent in both groups. Those on codeine and acetaminophen had a significantly higher incidence of somnolence (24% vs. 17%) and constipation (21% vs. 11%). The tramadol-acetaminophen combination also provides symptomatic relief as add-on therapy in OA patients receiving NSAIDs or COX-2 agents as baseline therapy.⁸⁰

Extended-release narcotic analgesics have been tested in clinical trials in OA. This approach is intended to achieve a lower level of peak-to-trough variability in the plasma concentration of the narcotic. An extended-release, once-a-day preparation of tramadol relieves pain in OA of the knee and hip.⁸¹ Extended-release oxymorphone dosed twice a day also provides relief in those with moderate to severe pain from OA of the hip or knee, as demonstrated by a VAS and the WOMAC composite index, as well as the subscales for pain, stiffness, and physical function.⁸²

Transdermal fentanyl, a narcotic analgesic, has been used in the treatment of moderately to severely symptomatic knee and hip OA. It relieved pain and improved function in clinical trials as judged by a VAS and the WOMAC physical function subscale.⁸³

Intra-articular Agents

Corticosteroids. Although there is no role for systemic corticosteroids in OA, local intra-articular corticoid preparations have a long history in the management of OA. Corticosteroids have been shown to downregulate the expression of adhesion molecules. This, in turn, can reduce cellular infiltration into the joint and subsequent inflammation. Corticosteroid injections slow macrophage-like cell infiltration of the synovium in OA.⁸⁴ The dose of steroid injected is determined by the volume of the joint being injected, with larger joints such as the knee receiving higher doses. The risk of joint infection is low if proper technique is employed. Postinjection flares due to corticosteroid crystal synovitis can occur.

There is a relative dearth of information from clinical trials of intra-articular corticosteroid injections. However, in one study, symptomatic benefit from corticosteroid injection for OA of the knee was demonstrated in a double-blind trial at 1 and 4 weeks postinjection.⁸⁵ Another trial

attempted to assess the possible disease-modifying effects of corticosteroids by randomizing 68 patients to corticosteroid or saline injections of the knee every 3 months for 2 years. At the study's end, there was no significant difference in rate of joint space narrowing; thus no case could be made for a disease-modifying effect of corticosteroid injections. There was a trend favoring pain relief in the corticosteroid group as measured by the pain subscale of the WOMAC.⁸⁶ A review of published studies of intra-articular corticosteroid injections in OA concluded that the short-term symptomatic benefits have been well established, with few adverse events, but long-term benefits have not been confirmed.⁸⁷

The specific corticosteroid compound used, the frequency of injections, and other factors related to the use of corticosteroid injections in OA vary widely and are heavily influenced by the training program the rheumatologist attended and where he or she practices.⁸⁸ In general, corticosteroid injections are believed to be most effective in patients with evidence of inflammation, effusions, or both. Because of concerns over possible deleterious effects, usually no more than four corticosteroid injections per year are given in a particular joint. Further discussion of arthrocentesis can be found in Chapter 54.

Hyaluronic Acid Derivatives. Synthetic and naturally occurring hyaluronic acid derivatives are administered intra-articularly. Although often mentioned as potential structure-modifying agents, these products are presently considered symptom-modifying drugs. Their molecular weights vary (from <100,000 to >1 million Svedberg units), depending on the preparation. They reportedly reduce pain for prolonged periods and may improve mobility.⁸⁹ Improvement in overall physical functioning has also been reported.⁹⁰ The mechanisms of action are not known. However, there is evidence of an anti-inflammatory effect (particularly at high molecular weight), a short-term lubricant effect, an analgesic effect by direct buffering of synovial nerve endings, and a stimulating effect on synovial lining cells, leading to the production of normal hyaluronic acid.⁹¹

Several preparations have been approved in the United States for OA of the knee. The injection regimens vary from five weekly injections to one injection depending on the product selected by the clinician for use.⁹² Pain relief has been the primary outcome in these studies with relief at 26 weeks postinjection for some. In one study, three weekly hyaluronic acid intra-articular injections provided comparable pain relief to a single corticosteroid intra-articular injection at 1-week follow-up; at 45 days' follow-up, hyaluronic acid was superior to the corticosteroid.⁹³ In a Canadian study, 102 patients with OA of the knee were randomized to three weekly intra-articular injections of hylan G-F (Synvisc), hylan G-F plus an NSAID, or NSAID alone. At 26 weeks, both groups receiving hylan G-F were significantly better than the group receiving NSAIDs alone.⁹⁴

Substantial clinical responses to the saline injections used as placebo in hyaluronic acid trials have sometimes made data interpretation challenging. In a double-blind, placebo-controlled trial, 495 patients with knee OA were randomized to receive five intra-articular injections of hyaluronic acid (Hyalgan) given 1 week apart, placebo, or naproxen (500 mg orally twice a day) and followed for 26

weeks.⁹⁵ Patients in the group receiving hyaluronic acid had significantly greater improvement in pain on the 50-foot walk compared with placebo, and more of them had a 20-mm or greater reduction in pain as judged by a VAS. At the conclusion of the trial, more hyaluronic acid–treated patients (47.6%) had slight pain or were pain free compared with placebo-treated (33.1%) or naproxen-treated (36.9%) patients. As expected, GI adverse events were significantly more common in the naproxen group than the hyaluronic acid and placebo groups.

Hyaluronic acid preparations have been tested in other randomized trials, with symptomatic relief of OA of the ankles, shoulders, and hips being reported.⁹⁶⁻⁹⁸ One multicenter, randomized, double-blind study, reported as an abstract, revisited the issue of disease modification with hyaluronic acid. Patients received three courses of three intra-articular knee injections of either hyaluronan or saline over the course of 1 year. Joint space width was assessed using standing, weight-bearing radiographs; 273 patients completed the trial and had complete data collection. This study failed to demonstrate a disease-modifying effect for hyaluronan therapy because the primary endpoint was not met. Both the active treatment group and the placebo group had similar joint space narrowing during the study period. In those with a joint space width of 4.6 mm or greater at entry, hyaluronan use led to slightly less joint space narrowing than saline (placebo, 0.55 mm \pm 1.04; hyaluronan, 0.13 mm \pm 1.05; P = .02).⁹⁹ These results have not been confirmed in other trials. Hyaluronic acid products continue to be actively investigated in shoulder joint OA, periarthritis,¹⁰⁰ and adhesive capsulitis.¹⁰¹

Nutraceuticals

Two nutritional supplements—glucosamine and chondroitin sulfate—have received significant attention (Table 100-3). Health food stores and the lay press rather dubiously proposed them as “cures for arthritis.” The mechanism of action of glucosamine sulfate is uncertain. Some *in vitro* experiments have shown stimulation of the synthesis of cartilage glycosaminoglycans and proteoglycans.^{102,103} Others have shown that glucosamine and *N*-acetylglucosamine inhibit interleukin (IL)-1 β – and tumor necrosis factor (TNF)–induced nitric oxide production in normal human articular chondrocytes.¹⁰⁴ *N*-acetylglucosamine also suppresses the production of IL-1 β and stimulates IL-6 and COX-2.

Glucosamine

Urinary excretion of glucosamine (and other glycosaminoglycans) has been investigated and found to be elevated in

both OA and rheumatoid arthritis.¹⁰⁵ Supplementation with glucosamine sulfate, an intermediate in mucopolysaccharide synthesis, has been tried both orally and intramuscularly as therapy for OA. Glucosamine sulfate (400 mg injected intramuscularly twice weekly for 6 weeks) reduced the severity of disease as judged by the Lequesne index when compared with placebo.¹⁰⁶ A randomized, double-blind, parallel-group study in knee OA compared 500 mg oral glucosamine sulfate three times a day with 400 mg ibuprofen three times a day for 4 weeks. The response to ibuprofen was more rapid, but at 4 weeks, there was no statistically significant difference in the response rate (reduction of at least 2 points in the Lequesne index).¹⁰⁷ No group in the study received higher, anti-inflammatory doses of ibuprofen. An NIH-sponsored trial is currently under way in the United States to more thoroughly study the symptom-relieving and possible structure-modifying properties of glucosamine. Meanwhile, some already advocate the use of glucosamine as part of the first line of therapy for symptomatic OA.¹⁰⁸

Glucosamine has also been compared with acetaminophen in an industry-sponsored trial. In the GUIDE trial, 318 patients with knee OA were randomized to glucosamine sulfate soluble powder 1500 mg once a day, acetaminophen 1000 mg three times a day, or placebo for 6 months. The main efficacy parameter was the 6-month change in the Lequesne index. At 6 months, the glucosamine group achieved significantly greater efficacy versus placebo. Those on acetaminophen failed to achieve a statistically significant benefit versus placebo by either the Lequesne index or WOMAC. There was no statistically significant difference between those on glucosamine and those on placebo on the basis of WOMAC outcomes.¹⁰⁹ Another clinical trial randomized 80 patients with knee OA to either glucosamine sulfate 1500 mg/day or placebo for 6 months. There was no difference between glucosamine and placebo in the primary variable of patients’ global assessment of pain in the affected knee.¹¹⁰ Another trial used a unique Internet-based recruiting system and followed 205 patients with knee OA randomized to glucosamine sulfate 1500 mg/day or placebo for 12 weeks.¹¹¹ The primary endpoint was the pain subscale of the WOMAC. At study conclusion, there was no difference in the groups with regard to pain, physical function, or overall WOMAC scores. Stratification by severity of OA, glucosamine product used, or use of NSAIDs did not alter the results. The Cochrane review of glucosamine therapy in OA analyzed a pool of 20 studies and 2570 patients. Pain and function improved by 28% and 21%, respectively, by the Lequesne index, compared with placebo. There was no improvement in the overall WOMAC pain and function scales. There has been speculation that these inconsistencies in study results may be due to a lack of standardization in glucosamine preparations.¹¹²

A recent discontinuation trial has added to the uncertainty about glucosamine’s efficacy. It found that 137 patients who had been clinically classified as moderate responders to glucosamine sulfate were equally likely to experience an OA flare whether they continued or discontinued the glucosamine. No statistically significant differences between the groups were noted in pain and WOMAC function scores after 6 months.¹¹³

Table 100-3 Nutraceuticals for Osteoarthritis

S-adenosyl methionine

Combination products containing both glucosamine and chondroitin have become popular in the United States, despite a dearth of clinical trial data. One small, placebo-controlled trial randomized patients with knee OA to receive a regimen of glucosamine hydrochloride (1000 mg), chondroitin sulfate (800 mg), and manganese ascorbate (152 mg) twice a day or placebo.¹¹⁴ Patients were evaluated at baseline and then every 2 months for 6 months using the Lequesne index of OA severity. At 4 and 6 months, those with mild to moderate radiographic OA of the knee showed significant improvement by the Lequesne index compared with those on placebo. In those with severe radiographic OA of the knee, no significant symptomatic benefit could be demonstrated. The study did not evaluate patients for structure or disease modification.

In the Glucosamine/Chondroitin Arthritis Intervention Trial (GAIT),¹¹⁵ 1583 patients with OA of the knee were randomized to placebo, glucosamine hydrochloride 1500 mg/day, chondroitin sulfate 1200 mg/day, celecoxib 200 mg/day, or glucosamine hydrochloride and chondroitin sulfate. The primary endpoint was the percentage of patients achieving at least 20% improvement on the WOMAC pain subscale at 6 months. The only statistically significant response was seen in those on celecoxib versus placebo (70.1% vs. 60.1%; $P = .008$). Patients were then stratified for baseline severity by WOMAC pain scores, most of them falling into the mild OA pain category. In a subgroup analysis, in those with moderate to severe OA pain (WOMAC pain, 301 to 400 mm), the combination of glucosamine hydrochloride and chondroitin sulfate was more efficacious than placebo as measured by a dichotomous response rate (positive = 50% improvement in pain): 79.2% versus 54.3% ($P = .002$). Analysis of the radiographic data from this trial failed to support the notion of a disease-modifying/slowing role for glucosamine, chondroitin sulfate, or the combination of these compounds.

From these results, it appears that patient selection may be important in maximizing any potential benefit from glucosamine or chondroitin therapy. The GAIT study also had a particularly high placebo response rate, which may reflect the enrollment of patients with less symptomatic OA and may have affected the results. It also used a glucosamine hydrochloride preparation instead of the glucosamine sulfate used in most other studies, particularly those that have demonstrated efficacy. This raises the question of whether the choice of glucosamine hydrochloride negatively affected efficacy in the trial. However, one small (142 patients) Chinese trial randomized patients with OA of the knee to glucosamine sulfate 1500 mg/day or glucosamine hydrochloride 1440 mg/day for 1 month.¹¹⁶ No efficacy differences were noted, with a clear majority of patients in each treatment arm achieving symptomatic improvement by Lequesne scores. The study had no placebo arm. Safety assessments continued for 2 additional weeks, with no significant adverse events reported. At present, it is still unclear whether glucosamine hydrochloride preparations have the same potential clinical benefits as glucosamine sulfate preparations. Additional investigations are necessary.

Two European trials tried to address the subject of disease modification with glucosamine. In one study, 212 patients with OA of the knee were randomized to receive placebo

or glucosamine sulfate (1500 mg/day) and were followed prospectively for 3 years.¹¹⁷ Fluoroscopically positioned, standing anteroposterior radiographs of the knees were taken at enrollment, 1 year, and 3 years. At 3 years, the treatment group had a joint space reduction of 0.06 mm, whereas the placebo group had a reduction of 0.31 mm. Whether this is a clinically meaningful difference in joint space is unclear. Those taking glucosamine also showed symptomatic benefit on the order of 20% to 25%, whereas those taking placebo had a slight worsening of symptoms, as judged by the WOMAC. There were no significant adverse events attributed to the use of the glucosamine sulfate. A second group of researchers randomized 202 patients to receive placebo or glucosamine sulfate (1500 mg/day) for 3 years.¹¹⁸ The width of the narrowest medial joint space of the tibiofemoral joint was measured serially, using visual assessments with a 0.1-mm graduated magnifying glass on standardized full-extension, weight-bearing anteroposterior radiographs of each knee. At 3 years, there was a significant difference in joint space width, with a decrease of 0.19 mm in the placebo group and an increase of 0.04 mm in the glucosamine sulfate group. Also, significantly greater improvements in the WOMAC score and the Lequesne index were seen in the glucosamine group. The favorable results of these studies have been questioned because of the radiographic technique used to assess joint space. At issue is whether the joint space seen on standing films of the knee might be significantly affected by the symptoms of OA (i.e., pain) and whether a semiflexed film would be preferable. In one study, investigators obtained baseline radiographs (after analgesic or NSAID washout) using both standing-extended and semiflexed, fluoroscopically positioned techniques in 19 patients with knee OA.¹¹⁹ Radiographs were then repeated 2 to 8 weeks later after reinstitution of analgesic or NSAID therapy. Joint space width increased with effective pain relief in highly symptomatic patients if measured by standing-extended radiographs. Using the semiflexed technique, there were no significant changes in joint space width related to severity of pain or responsiveness to pain therapy. This suggests that data obtained using the standing-extended radiographic technique may need to be revisited because the results may represent a therapeutic intervention's effect on symptoms (pain) rather than a disease-modifying effect. More recent, ongoing trials have changed to the semiflexed, fluoroscopically positioned knee radiograph to assess potential disease modification.¹²⁰

Chondroitin Sulfate

Oral chondroitin sulfate, a glycosaminoglycan composed of units of glucosamine with attached sugar molecules (molecular mass of around 14,000), has also been used as therapy for hip and knee OA. Its mechanism of action is unknown. A double-blind, placebo-controlled study included a 3-month treatment phase followed by a 2-month treatment-free phase. The major outcome parameter was NSAID consumption. Those receiving chondroitin sulfate used fewer NSAIDs than the controls both at the completion of treatment and in the treatment-free phase.¹²¹ Another study compared chondroitin sulfate to diclofenac sodium. One group received chondroitin sulfate (400 mg three times a day) and the other diclofenac sodium (50 mg three times a

day). Each group was also changed over to placebo at some point. The chondroitin group received the active drug for 3 months, whereas the diclofenac group received it for only 1 month before being switched to placebo. For months 4 through 6, both groups took only placebo. The diclofenac group had a quicker response to therapy, whereas the chondroitin group had a more prolonged improvement as measured by the Lequesne index, VAS for pain, four-point scale for pain, and paracetamol use (rescue medication).^{114,122} This study raises questions because of the different lengths of treatment with active drug in each group. Further studies are necessary.

One study evaluated chondroitin sulfate as a disease-modifying intervention. Three hundred patients were enrolled and randomized to chondroitin sulfate 800 mg daily or placebo for 2 years.¹²³ Joint space width was assessed using anteroposterior semiflexed radiographs. Pain and function were assessed as secondary endpoints. In the placebo group, the mean change in joint space width was 0.07 mm/year, while in the treatment group, the mean change was 0.00. A similar difference was noted when the minimum joint space width was evaluated. The differences were statistically significant (mean joint space width, $P = .04$; minimum joint space width, $P = .05$), but the clinical relevance remains unclear. The changes in radiographic progression were not matched by similar differences when pain and function were analyzed. The treatment group achieved improvement in all WOMAC subscales of pain, function, and stiffness, but a statistically significant difference could not be shown. It has been suggested that the overall low baseline WOMAC scores created difficulties in assessing for clinical improvement.

Other Nutraceuticals

Ginger extracts have been popular “natural” remedies for OA for some time.¹²⁴ Most of the world’s ginger comes from China, and its “medicinal” use dates back more than 2000 years. Ginger actually contains small amounts of salicylate.¹²⁵ In some animal models, ginger has been shown to have inhibitory effects on COX and lipoxygenase.¹²⁶ One study with 247 evaluable patients revealed a small but statistically significant reduction in knee pain on standing (63% vs. 50%; $P = .048$) after taking ginger.¹²⁷ Reduction in knee pain after a 50-foot walk was also significant. Use of acetaminophen was reduced in the ginger-extract group, but the difference was not statistically significant. The extract was well tolerated, except for GI events such as dyspepsia, nausea, and eructation, which were increased over placebo. The question remains whether benefits observed represent a clinically relevant effect.

Some of the more unusual agents proposed as structure or disease modifiers in OA are oral preparations of avocado and soy unsaponifiables (ASUs). These compounds are derived from unsaponifiable residues of avocado and soya oils mixed in a 1:2 ratio. In vitro studies on cultured chondrocytes showed partial reversal of IL-1 β effects. The roles of IL-1 β in OA are thought to include inhibition of prostaglandin synthesis by chondrocytes and stimulation of matrix metalloproteinases (MMPs) and nitric oxide production. MMPs and nitric oxide can degrade cartilage matrix and cause chondrocyte apoptosis. Use of ASUs also reportedly

results in inhibited production of IL-6, IL-8, and MMPs and stimulation of collagen synthesis. Increased aggrecan synthesis has been reported as well.¹²⁸ The mechanism of action is unknown, as is the active ingredient in ASUs.¹²⁹ Symptomatic benefit in double-blind human trials in OA of the hip and knee has been reported.¹³⁰ However, a double-blind, placebo-controlled trial in OA of the hip failed to show disease modification in the overall population, although a post hoc analysis reported benefit in those with more advanced OA at baseline. Some abstract presentations have suggested structure or disease modification in human hip OA.¹³¹

Other nutritional supplements such as cat’s claw and shark cartilage have become entrenched in regional and international popular cultures. Many people take them, despite limited or no data to support their use. A small, placebo-controlled trial showed improvement of OA pain with activity in those taking cat’s claw extracts.¹³² Shark cartilage contains a small amount of chondroitin sulfate.¹³³ S-adenosyl methionine (SAME), a methyl group donor and oxygen radical scavenger, is often touted as a remedy for OA, although little evidence of its effectiveness has been published.^{134,135} In one double-blind, placebo-controlled study, two centers reported differing results. One center reported reductions in overall pain and rest pain, whereas the other showed no significant difference between the test group and placebo group.¹³⁶ Another small, double-blind, placebo-controlled crossover study of 61 patients compared oral SAME 1200 mg/day with oral celecoxib 200 mg/day for 16 weeks. After the first month of phase I, celecoxib provided superior pain relief that was statistically significant. By the end of the second month, however, there was no statistically significant difference between the groups.¹³⁷ There is insufficient evidence to recommend the use of these products in the treatment of OA.

Other Potential Structure- or Disease-Modifying Therapies

The term *chondroprotective* has been used to describe structure- or disease-modifying agents. This is a misnomer, however, because the goal is to protect the entire joint (not only the cartilage) from the arthritic process. A workshop of the Osteoarthritis Research Society recommended that the term *structure-modifying drugs* be used for medications that previously would have been classified as chondroprotective.¹³⁸ These drugs are intended to prevent, retard, stabilize, or even reverse the development of OA. Recently, the term *disease-modifying osteoarthritis drug* (DMOAD) has been used for any such agent (Table 100-4). Such a disease-modifying effect in OA would require prolonged observation, given the typically slow progression of OA. Therefore clinical trials in this area have been challenging, with most being designed for at least 2½ to 3 years of follow-up. Progress in the methodology used to assess structure and disease modification may shorten the length of these trials. Radiographic assessments of joint space such as fluoroscopically positioned anteroposterior radiographs of the knee or magnetic resonance imaging may be useful in this regard.¹³⁹

Unfortunately, to date, no drug has been conclusively proved to be structure or disease modifying. Although this chapter focuses on medication-based therapies, other

Table 100-4 Potential Structure- and Disease-Modifying Drugs in Osteoarthritis

Tetracyclines
Metalloproteinase or collagenase inhibitors

approaches such as osteochondral grafts of chondrocytes, donation of stem cells, or both, with eventual differentiation into bone and cartilage, are in various stages of development.¹⁴⁰ Potential structure- or disease-modifying interventions under investigation include collagenase inhibitors, polysaccharides, and growth factor and cytokine manipulation.

Tetracyclines, apart from any antimicrobial effect, are inhibitors of tissue metalloproteinases, perhaps owing to their ability to chelate calcium and zinc ions. There has also been research into the potential role of nitric oxide in the mechanism of action of the tetracyclines.¹⁴¹ Minocycline, a tetracycline-family antibiotic, has been used in the management of rheumatoid arthritis.¹⁴² Doxycycline, another tetracycline derivative, has been shown to inhibit articular cartilage collagenase activity.^{143,144} Doxycycline has also reduced the severity of OA in canine models. In one study, there was preservation of medial femoral condyle cartilage in treated dogs compared with the untreated group. Other lesions such as medial trochlear ridge cartilage damage, superficial fibrillation of the medial tibial plateau, and osteophytosis were unaffected by treatment. Collagenolytic activity and gelatinolytic activity, however, were reduced to 20% and 25% of their previous levels, respectively, compared with untreated dogs. In an in vitro model, doxycycline not only reduced collagenase and gelatinase activity in cartilage but also prevented proteoglycan loss, cell death, and deposition of type X collagen matrix.¹⁴⁵

A multicenter, double-blind, placebo-controlled trial using doxycycline for structure or disease modification in obese female subjects with OA of the knee has been completed. In this study, 431 obese women with unilateral OA of the knee were treated with doxycycline 100 mg twice daily or placebo. The primary endpoint was radiographic progression. The minimum joint space width was assessed by fluoroscopically positioned anteroposterior, semiflexed, standing radiographs. Pain and function were evaluated as secondary endpoints. Progression of minimum joint space width at 30 months was 0.3 ± 0.60 mm in the treatment group and 0.45 ± 0.70 mm in the placebo group ($P = .017$). Imaging of the contralateral knee was also performed at baseline and at 30 months. Progression in the contralateral knees was no different between the groups.¹⁴⁶ Secondary outcomes of pain and function were also recorded by WOMAC, VAS, 50-foot walk pain, and global assessment. Mean overall scores for pain were not significantly different between the groups. However, the frequency with which patients reported 20% or greater increase in knee pain was less in the treatment group ($P < .05$). Although a small disease-modifying effect was demonstrated in the target

knee, no such effect could be demonstrated in the contralateral knee. Thus the implications of these findings for clinical practice are uncertain. Other compounds with collagenase-inhibiting properties are being developed and investigated as structure- or disease-modifying agents not only in OA but also in rheumatoid arthritis.¹⁴⁷

Glycosaminoglycan polysulfuric acid (GAGPS; Artep-arone or Adequan) has been purported to work by reducing the activity of collagenase. It is a highly sulfated glycosaminoglycan, with a molecular weight ranging from 2000 to 16,000,¹⁴⁸ derived from bovine tracheal cartilage. In a canine model of OA, GAGPS was administered intra-articularly twice weekly for 4 weeks.¹⁴⁹ Four weeks after completion of the GAGPS treatment, medial femoral condylar lesions had developed to a lesser degree in the treated group than in saline-treated dogs. Swelling, an indicator of collagen network integrity, remained near control levels in the treatment group. In humans, OA of the knee was studied in a 5-year trial. There was improvement in multiple measured parameters including less time lost from work.¹⁵⁰ Another double-blind, placebo-controlled trial evaluated GAGPS in 80 patients with OA of the knee; patients received two series of five intra-articular injections of 25 mg (0.5 mL) GAGPS at 1-week intervals. At 14 weeks, 31% of the GAGPS group had improvement as judged by the Lequesne index, compared with 15% in the placebo group.¹⁵¹ Potential allergy and heparin-like effects were observed. GAGPS is available in the United States for equine, but not human, use.

Another extract, a glycosaminoglycan-peptide complex (GP-C) known as *Rumalon*, has been investigated. It is a highly sulfated polysaccharide derived from bovine tracheal cartilage and bone marrow and is administered intramuscularly.¹⁵² It has been shown to increase the levels of tissue inhibitor of metalloproteinases (TIMPs).¹⁵³ A randomized, placebo-controlled trial selected patients with hip or knee OA to receive 10 courses of injections of placebo or GP-C (2 mL) over 5 years (two courses per year). Each course consisted of 15 injections given twice weekly. GP-C failed to demonstrate a structure- or disease-modifying effect.¹⁵⁴ In addition, there were no statistical differences favoring the active treatment group when measured by the Lequesne index, pain on passive motion, or consumption of NSAIDs. GP-C is available in parts of Europe and South America.

Pentosan polysulfate (Cartrofen) is a purified extract of beech hemicellulose administered intramuscularly or orally as a calcium salt. It can inhibit granulocyte elastase and has inhibited the catabolism of aggrecan in cartilage explants.¹⁵⁵ Experimental studies in animal models suggest that it helps preserve cartilage proteoglycan content and retards cartilage degradation.^{156,157} However, a recent blinded, placebo-controlled study using an oral preparation in a dog model failed to demonstrate either a symptomatic benefit or a structure- or disease-modifying effect.¹⁵⁸

Diacerein and its active metabolite rhein are anthraquinones related to senna compounds.¹⁵⁹ They inhibit the synthesis of IL-1 β in human OA synovium in vitro, as well as the expression of IL-1 receptors on chondrocytes.¹⁶⁰ No effects have been reported on TNF or its receptors. Collagenase production and articular damage have been reduced in animal models.¹⁶¹⁻¹⁶³ Early human clinical trials have shown improved pain scores compared with placebo and

comparable efficacy to NSAIDs but a slower onset of action. Diarrhea is the main potential side effect. On the strength of these prior trials, diacerein has been proposed as a slow-acting symptom-modifying and perhaps structure- or disease-modifying drug for OA.

A double-blind, randomized, placebo-controlled trial looking at the efficacy and safety of diacerein enrolled 484 patients with symptomatic knee OA.¹⁶⁴ They were randomized to receive placebo, diacerein 25 mg twice a day, diacerein 50 mg twice a day, or diacerein 75 mg twice a day. Using intent-to-treat analysis, diacerein 100 mg/day was significantly superior to placebo ($P < .05$) by the primary endpoint—patients' assessment of pain on movement at week 24 (-18.3 ± 19.3 mm vs. -10.9 ± 19.3 mm). It was also superior on the basis of WOMAC and disability scores. However, no statistical difference was detected in the primary endpoint between placebo and 50 mg/day diacerein (-15 ± 21.0 mm) or 150 mg/day diacerein (-14.3 ± 23.7 mm).

There have also been investigations into the potential structure- or disease-modifying attributes of diacerein in OA.¹⁶⁵ In one study, 507 patients with OA of the hip (according to American College of Rheumatology criteria) were randomized to receive either diacerein (50 mg orally twice a day) or placebo for 3 years. Patients were followed with yearly pelvic radiographs to assess hip joint space. Using completer analysis, the diacerein patients showed a significantly lower rate of radiographic progression (0.18 vs. 0.23 mm/year). Using intent-to-treat analysis, a smaller proportion of those taking diacerein had significant joint space loss (defined as loss of ≥ 0.5 mm) during the study (50.7% vs. 60.4%). Unfortunately, almost 50% of the patients failed to complete the 3-year study. In the placebo group, the principal reason for discontinuation was lack of efficacy, whereas in the diacerein group, it was adverse effects such as diarrhea. Curiously, the symptom-relieving effect of diacerein observed in prior studies could not be confirmed in this one. A recent meta-analysis of clinical trials of diacerein in OA concluded that available clinical evidence supports pain relief in hip and knee OA. There was no analysis of a disease-modifying effect.¹⁶⁶

Potential methods of intervention in OA include growth factor and cytokine manipulation.¹⁶⁷ Cytokines such as IL-1 and TNF are produced by the synovium and contribute to inflammation within osteoarthritic joints.¹⁶⁸ Moreover, there may be deficient expression of naturally occurring anti-inflammatory compounds such as IL-1 receptor antagonist (IL-1Ra) by the chondrocytes of patients with OA.¹⁶⁹ In some cases, increased nitric oxide production by OA articular chondrocytes may inhibit IL-1Ra synthesis.¹⁷⁰ In a dog model of OA, IL-1Ra therapy reduced the expression of collagenase-1 in cartilage.¹⁷¹ The severity of cartilage lesions is also diminished.¹⁷² In a rabbit model of OA, transfer of the IL-1Ra gene to joints prevented OA progression.¹⁷³ The effect of IL-1 blockade in humans with OA through the use of IL-1Ra is currently being investigated. Induction of repair in partial-thickness articular cartilage lesions by the timed release of transforming growth factor- β using liposomes has been attempted in an animal model. There was an increase in the cellularity of the defects, which were populated by cells of mesenchymal origin from the synovial membrane. The repaired cartilage resembled

hyaline cartilage, and its integrity persisted up to 1 year after surgery.¹⁷⁴ Combination therapy is another alternative. In a study of canine-induced OA, sodium pentosan polysulfate, when combined with insulin-like growth factor-I, reduced stromelysin activity and increased TIMP.¹⁷⁵

Initial attempts at gene therapy are intriguing. The control of genes such as TIMP and MMPs would, in theory, provide the opportunity to modulate the patient's disease. As previously noted, gene expression of IL-1Ra has already been tried in rabbits and dogs, as well as in an equine model of OA using an adenovirus vector.¹⁷⁶ Use of gene transfer-mediated overexpression of IL-1 β decoy receptor has also been contemplated.¹⁷⁷ Chondrocyte and stem cell transplants into articular cartilage defects have been tried as well. Chondrocytes transplanted (expressing a previously transfected β -galactosidase gene) into human cartilage explants survived up to 45 days in vitro in one trial.^{178,179} Transfection of chondrocytes with the galactosidase gene has been successful both before and after transplantation.

Surgical Intervention

Surgical interventions in OA usually consist of osteotomies or joint replacements. Osteotomies can be effective pain-relieving interventions and can delay the need for joint replacement surgery in selected patients. These tend to be younger subjects with OA.

Joint replacement surgery (joint arthroplasty) is effective in providing pain relief and restoring function in many patients with OA. Hip and knee joint replacements are most common. Indications for surgery include pain that is refractory to the previously discussed interventions and significant impairment of the patient's daily life. Therefore patients should be the key decision makers because they are the ones who must weigh the severity of symptoms and impairment. Patients undergoing replacement surgery should be deemed able to undertake the rehabilitation necessary to regain reasonable use of the joint involved. Infections are rare but do occur. Joint replacements have a typical life span of between 10 and 15 years. Revision surgery may be necessary, particularly in a relatively young patient who outlives the useful life of the prosthesis.

Other potential rationales for surgical intervention in OA include removal of loose bodies, stabilization of joints, redistribution of joint forces (e.g., osteotomy), and relief of neural impingement (e.g., spinal stenosis, herniated disk). The value of arthroscopic débridement or lavage in OA has been questioned. A recent randomized, blinded trial failed to demonstrate significant symptomatic benefit in OA of the knee.

SUMMARY

The treatment of OA includes a variety of possible non-pharmacologic and pharmacologic interventions. Treatment should be tailored to the individual and consists of a combination of modalities. These provide symptom relief but have no proven effect on the progression of disease. Structure and disease modification has yet to be achieved in OA. Trials that are under way could determine whether this is a realistic goal. Claims of structure or disease modification in OA should not be made for any drugs until

well-designed, double-blind, placebo-controlled trials demonstrate that this is so. It is hoped that with the eventual advent of disease-modifying OA drugs, treatment will eventually consist of a combination of symptom-relieving and disease-modifying interventions.

Metabolic Bone Disease

NANCY E. LANE

KEY POINTS

Osteoporosis is a disease defined by low bone density and deterioration of microarchitecture, which reduces bone strength and increases fracture risk.

Major clinical risk factors for osteoporotic fractures include older age, low weight, family history of hip fracture, fracture occurring after age 50, glucocorticoid use, and inability to rise from a chair without assistance. More than 50% of osteoporosis in men results from secondary causes.

Postmenopausal and age-related bone loss results from an uncoupling of bone remodeling such that bone resorption is greater than bone formation, resulting in a net loss of bone.

Polymorphisms in antagonists of the wnt/B catenin signaling pathway that result in a gain of function (e.g., LRP5) are associated with a reduced risk of osteoporosis.

Biochemical markers measured in the serum including C and N telopeptide cross-links of type I collagen correlate with osteoclast activity on the bone surface.

Evaluation for risk of osteoporotic fractures with the Fracture Assessment Index (FRAX) for postmenopausal women and men is critical to determine individuals with high enough 10-year fracture risk (hip and major osteoporotic fracture sites) to warrant treatment.

Treatment of high-turnover osteoporosis from estrogen deficiency with antiresorptive agents (estrogen, raloxifene, and bisphosphonates—alendronate, risendronate, zoledronic acid, ibandronate, denosumab) and an anabolic agent (recombinant human parathyroid hormone 1-34) can reduce incident vertebral fractures.

Parathyroid hormone (PTH) increases osteoblast maturation and life span, increases trabecular bone mass and cortical thickness, improves bone strength, and decreases fractures. Antiresorptive therapy is necessary after a full course of PTH to maintain newly formed bone mass.

Glucocorticoid-induced bone loss results from increased osteoclast activity and reduced osteoblast activity and is most severe in the first 6 months of therapy. Bisphosphonate treatment can prevent fractures.

Aromatase inhibitors reduce serum estrogen and result in rapid bone loss in postmenopausal women on adjuvant breast cancer therapy.

Gonadotropin-releasing hormone agonists decrease testosterone and estrogen levels and cause bone loss in men being treated for prostate cancer.

Osteoporosis is characterized by low bone density and a deterioration of bone microarchitecture that reduces bone strength and increases the risk of fracture. The hallmark of osteoporosis is the loss of bone mineral and bone matrix that results in maintenance of a normal mineral-to-matrix ratio. Bone consists of an organic matrix (collagen and noncollagenous proteins) and an inorganic mineral component (calcium and phosphate in hydroxyapatite crystals; see Chapter 4). Normally, bone turnover is tightly coupled with osteoclast-mediated bone resorption followed by osteoblast-stimulated bone formation. This delicate balance in bone remodeling results in no net change in skeletal mass. Osteoblasts synthesize osteoid—bone matrix that subsequently undergoes mineralization and becomes mature bone matrix. The skeleton contains approximately 80% cortical bone, which is concentrated in the appendicular skeleton and femoral neck, and 20% more metabolically active trabecular bone, which is located in the spine, epiphyses, and pelvis. Osteoporosis is characterized by reduced bone strength usually accompanied by a reduction in bone mass. Osteomalacia encompasses disorders in which there is decreased mineralization of bone matrix. Paget's disease is a skeletal disorder characterized by increased rates of bone turnover with the development of disorganized woven bone.

OSTEOPOROSIS

Epidemiology and Clinical Signs

Osteoporosis, the most common metabolic bone disease, affects 200 million individuals worldwide. Approximately 28 million Americans have osteoporosis or are at risk for it. Osteoporosis, or “porous bone,” is a “disease characterized by low bone mass and structural deterioration of bone tissue, leading to bone fragility and an increased susceptibility to fractures, especially of the hip, spine and wrist.”¹ Although usually asymptomatic, osteoporosis can produce loss of height, pain, dowager's hump, and increased risk of fracture. After 50 years of age, there is an exponential rise in fractures, such that 40% of women and 13% of men develop one or more osteoporotic fractures in their lifetimes. In the United States alone, there are more than 1.5 million osteoporotic fractures annually including 250,000 hip, 250,000 wrist, and 500,000 vertebral fractures. Hip fractures are associated with a 12% to 24% mortality rate in women and a 30% mortality rate in men within the first year of fracture, and 50% of patients are unable to ambulate independently and require long-term nursing home care.² These numbers will continue to grow exponentially as the elderly population of industrialized nations increases.

Bone accretion occurs during adolescence, when there is a large increment in bone mass. Peak bone density is normally achieved after puberty and into the third decade of life. However, by age 22, most individuals have achieved nearly all of their peak bone mass. At menopause, an acceleration of bone loss usually occurs over approximately 5 to 8 years, with an annual 2% to 3% loss of trabecular bone and a 1% to 2% loss of cortical bone. Both men and women lose bone with age. Over a lifetime, women lose approximately 50% of trabecular and 30% of cortical bone; men generally lose two-thirds of these amounts.³ Osteoporosis was previously thought to be a silent disease that was part of the normal aging process. However, the advent of bone densitometry has made it possible to accurately and reproducibly identify patients at risk for osteoporosis so that prevention and treatment strategies can be instituted to reduce fractures. With a health care expenditure of \$13.8 billion annually for osteoporosis-related fractures and a projected threefold rise in these costs over the next 40 years in the United States, the institution of effective prevention and treatment strategies to reduce fractures is of great importance.^{1,4}

Pathophysiology of Menopausal and Age-Related Bone Loss

Bone is constantly undergoing remodeling, whereby areas of bone resorption produced by osteoclastic action are replaced by bone laid down by osteoblasts. Osteoporosis results from an imbalance between bone resorption and formation. The initiation of bone remodeling is still being debated; however, the osteocytes, or terminally differentiated osteoblasts, located within the bone matrix and connected to one another and the bone surface may release chemical mediators that attract osteoclasts to the bone surface (Figure 101-1). Osteoclasts originate from the colony-forming unit granulocyte-monocytes, are attracted to the bone surface, attach to bone matrix, and resorb bone tissue. Generally, bone resorption is rapid, and a resorption pit is formed within 10 to 14 days. After resorption is complete, osteoblasts, derived from the bone marrow stromal cells, attach to the resorbed bone surface and produce osteoid, which is then mineralized. Bone formation can take up to 3 or 4 months. Therefore a normal bone remodeling cycle in adults can last 4 to 6 months (see Figure 101-1A). A number of metabolic changes such as estrogen deficiency, immobilization, metabolic acidosis, hyperparathyroidism, and systemic and local inflammatory diseases can increase osteoclast number and activity, uncoupling bone turnover. This results in greater bone resorption than bone formation and a net loss of bone tissue. New data show that a number of local factors in bone affect the regulation of bone formation and resorption and the coupling of these processes. These include insulin-like growth factors (IGFs), interleukins (IL-1, IL-6, and IL-11), tumor necrosis factor (TNF), receptor activator of nuclear factor κ B ligand (RANKL), and transforming growth factor (TGF).⁵ Animal studies have shown that IL-1, IL-6, and TNF knockout mice do not lose bone with estrogen deficiency.⁶ In addition, inflammatory arthritis animal models find that TNF, IL-1, and IL-6 are all strong stimulators of osteoclastic bone resorption. This link between the immune system and the maintenance

of bone mass is intriguing, but additional work is required before we can understand its significance.

A number of mechanisms underlie primary osteoporosis including a low peak bone mass as a young adult and rapid bone loss during menopause. Factors contributing to age-related bone loss include impaired calcium absorption with age, a compensatory rise in parathyroid hormone (PTH) levels, and greater resorption than formation of bone. Estrogen deficiency is associated with the release of cytokines including RANKL, IL-1, IL-6, and TNF, which leads to the recruitment and stimulation of osteoclasts in the marrow and increased production of bone-resorptive cytokines, which may contribute to menopause-related bone loss.⁵ Estrogen therapy, however, inhibits IL-1 release, and in oophorectomized rats and mice, an inhibitor of IL-1 (the IL-1 receptor antagonist) suppresses bone loss.⁶ IL-6 levels also increase with age in human marrow cultures⁷ and in peripheral monocytes. IL-1 and TNF induce the production of IL-6 from osteoblasts and stromal cells. Further evidence supporting a role of IL-6 in bone turnover includes data showing that oophorectomized IL-6 knockout transgenic mice do not lose bone. Two other proteins have been identified that influence osteoclast activity: osteoprotegerin (OPG) and RANKL, which are produced by osteoblasts.⁸ Estrogen deficiency increases osteoblast production of RANKL, which stimulates maturation and activity of osteoclasts by attaching to RANKL on the surface of immature and mature osteoclasts. Simultaneously, estrogen deficiency decreases osteoblast production of OPG, the decoy receptor that reduces RANKL production and activity. Adenoviral delivery of OPG ameliorates bone resorption in a mouse ovariectomy model of osteoporosis.⁸ Both preclinical animal models and clinical trials of women with low bone mass have been completed and demonstrate that inhibition of RANKL with a monoclonal antibody (RANKL inhibitor) prevents estrogen-deficiency bone loss.⁹

In addition, a number of genetic, nutritional, and lifestyle risk factors predispose to the development of osteoporosis. Whites and Asians are at risk for low bone mass and osteoporosis, whereas African-Americans have a higher bone density and one-third to one-half the number of fractures.^{1,8,9} Some studies show that African-Americans have lower vitamin D and urinary calcium levels, higher PTH levels, and skeletal resistance to the effects of PTH on bone.¹⁰⁻¹² Studies in twins and families show that up to 80% of the variance in bone mass is accounted for by genetic factors.¹³ A maternal history of hip fracture, for example, is associated with a twofold increased risk of a hip fracture.¹⁴ Data from Uitterlinden and colleagues¹⁵ show that the gene encoding collagen type IA1 is associated with low bone density with increasing age and an increased risk of fracture. In the ss allele group, bone density was 12% lower at the femoral neck and 20% lower at the lumbar spine than that in the SS group, indicating an increased gene-dose effect with increasing age. However, COLIA1 is associated with a lower baseline bone density and not an increased rate of bone loss. Further, genetically determined architectural features of bone such as a long hip axis length may contribute to increased fracture risk; conversely, a short hip axis length confers some protective effect.¹⁶ Recently, a family has been described whose members have high bone mass but are otherwise phenotypically normal. This family has a

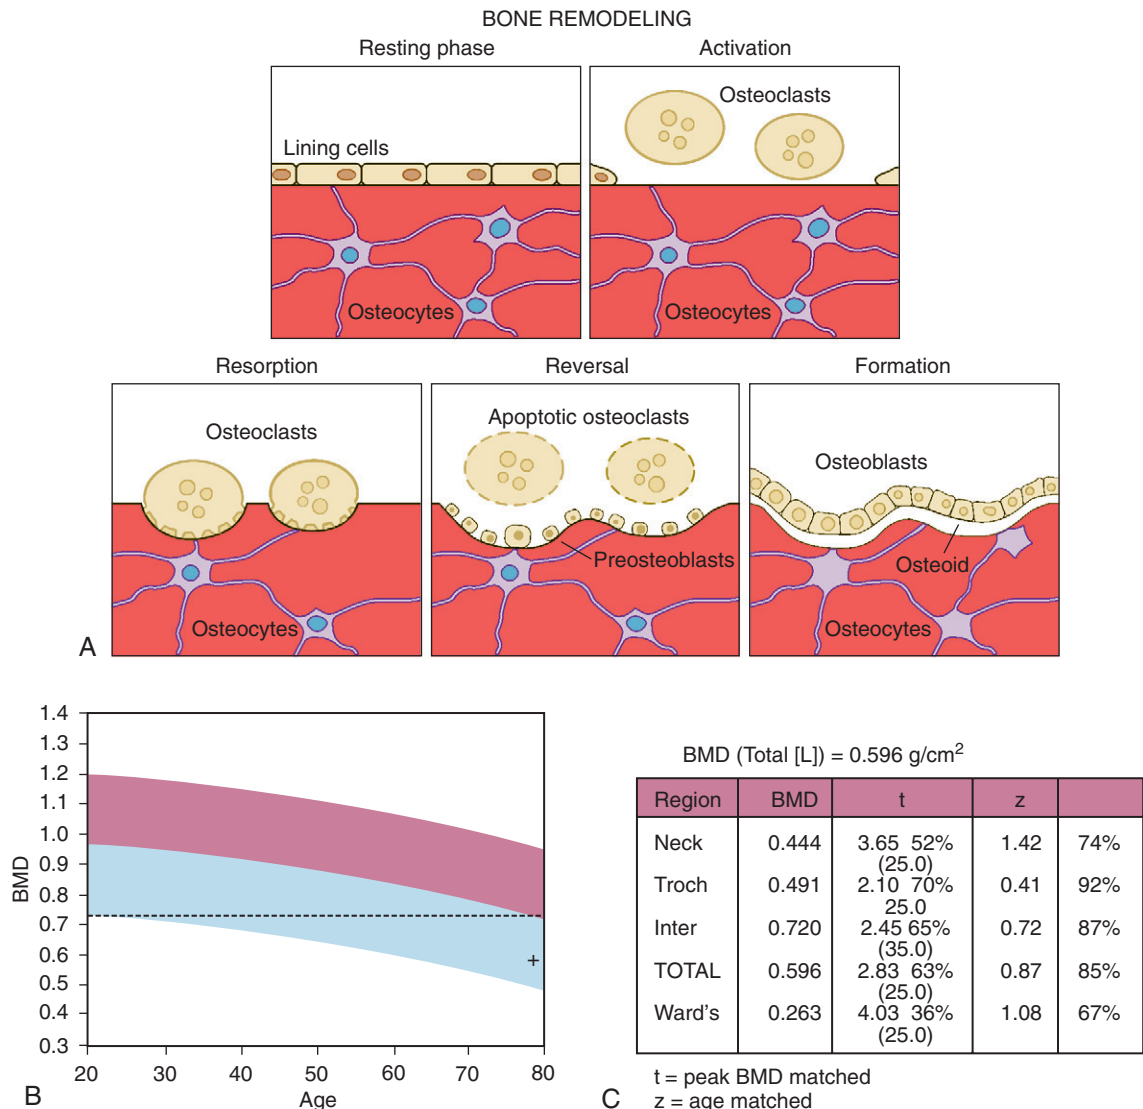

Figure 101-1 A, Bone remodeling cycle. Osteocytes most likely release chemicals to the bone surface that attract osteoclasts. Osteoclasts attach to the bone matrix, create a tight ring, and release acid that lowers the pH and dissolves the mineral from the bone matrix. After the mineral is released, the demineralized matrix is broken down. The osteoclast leaves the bone surface, and an osteoblast is attracted to the area of the bone that was resorbed. The resorption phase is about 10 to 14 days. Osteoblasts produce new bone, or osteoid, that fills in the resorption pit. Also, some of the osteoblasts are left within the bone matrix as osteocytes. The osteoid mineralizes over about 3 months, and the bone remodeling cycle is complete. **B and C,** The bone density of a postmenopausal woman is compared with that of both young, normal controls and age- and gender-matched controls. The t and z scores represent the number of standard deviations below young, normal controls and age-matched controls, respectively. Because the bone density provides a gradient of fracture risk, therapies can be instituted to prevent the development of osteoporosis or to treat patients at increased risk for fracture. BMD, bone mineral density.

mutation (an amino acid change) in the low-density lipoprotein receptor-related protein 5 (LRP5). Using in situ hybridization to a rat tibia, expression of LRP5 was detected in areas of bone involved in remodeling. Additional studies have reported that this LRP5 mutation increases wnt signaling, which may alter bone mass through a primary defect of bone formation. Individuals with this mutation demonstrate normal levels of bone resorption, but specific markers of bone formation are strikingly elevated. The observation that LRP5 is expressed at high levels in osteoblasts is consistent with its having a role in this area. Further work is now required to determine whether other mutations in the chromosome containing the LRP5 segment are

associated with a variation in bone density in the general population.^{17,18}

Recently, genome-wide scans have been performed in a number of cohorts and have found a number of single nucleotide polymorphisms (SNPs) that are associated with osteoporosis (fracture or bone mineral density [BMD] associations). They include VDR, ESR1, ESR2, LRP5, LRP4, SOST, GRP177, OPG, RANK, RANKL, COL1A, SPP1, ITGAI, SP7, and SOX6, which can be reasonably assigned as confirmed or replicated, and another 30 or so genes as promising candidates. Of note, confirmed and promising genes are clustered in three biologic pathways: the estrogen endocrine pathway, the wnt/beta-catenin signaling pathway,

and the RANKL/RANK/OPG pathway. New biologic pathways will certainly emerge when more osteoporosis genes are identified and validated.^{18a} Other risk factors for osteoporosis, as enumerated in Table 101-1, include low body weight and reduced gonadal steroid levels.¹³ Lifestyle factors that may contribute to the development of osteoporosis include cigarette smoking, excessive alcohol intake, reduced physical activity, and inadequate calcium intake, according to some reports. Cigarette smokers have poorer health than nonsmokers, impaired calcium absorption, lower estrogen levels, earlier menopause, and more fractures, and they exercise less; smoking cessation reverses this risk of osteoporosis.

In a large, prospective study of 9516 women older than 65 years, the following lifestyle factors significantly increased the risk of hip fracture: no walking for exercise, intake of more than two cups of coffee daily, current use of long-acting benzodiazepines and anticonvulsant drugs, current weight less than weight at age 25 years, height greater than 5 feet 7 inches, age older than 80 years, fracture since age 50 years, inability to stand from a chair without using arms, poor depth perception, and self-evaluation of health as fair to poor.¹⁴ Low bone density in conjunction with a fall or trauma predisposes an individual to a fracture. Poor health and compromise of neuromuscular function increase the risk of osteoporosis and falls, which in turn increase the risk of hip fracture.¹⁴ Importantly, elderly white women with both a low bone mass and more than two risk factors have a nearly 20-fold increased risk for fracture.

Secondary causes of bone loss that can affect women and men of all ages and races are listed in Table 101-2. Glucocorticoid therapy is the most common secondary cause of bone loss. Osteoporotic fractures develop in an estimated 30% to 50% of glucocorticoid-treated patients.¹⁹ Glucocorticoid therapy causes bone loss through a number of different mechanisms such as producing a negative

Table 101-1 Risk Factors for Osteoporosis

Primary
Previous fracture after age 30
Family history of hip fracture
Cigarette smoking
Weight <127 lb
Low bone mineral density
Secondary
Nonmodifiable
White race
Advanced age
Frailty or poor health
Dementia
Modifiable
Low calcium intake
Eating disorder
Low testosterone levels (men)
Premenopausal estrogen deficiency (amenorrhea >1 yr or menopause at age <45 yr)
Excessive alcohol intake
Physical inactivity
Impaired vision
Neurologic disorder
Lack of sunlight exposure

calcium balance through impaired intestinal calcium absorption, increasing urinary calcium excretion, decreasing bone formation, increasing bone resorption by stimulating osteoclast activity by macrophage colony-stimulating factor, and suppressing endogenous gonadal steroid production.¹⁹ Therapy with glucocorticoids leads to an early and, in some instances, dramatic loss of trabecular bone, with less effect on cortical bone. In hyperthyroidism (Graves' disease or toxic nodule) or supraphysiologic therapy with thyroid hormone, the ensuing accelerated bone turnover may produce a reduction in bone mass when the thyroid-stimulating hormone level is suppressed, even when thyroid hormone levels are within the normal range.²⁰ Athletic amenorrhea, anorexia nervosa, and other hypogonadal states including the use of gonadotropin-releasing hormone agonists^{21,22} may result in bone loss. In addition to estrogen deficiency, women with anorexia nervosa have low levels of IGF-I and reduced levels of adrenal androgen

dehydroepiandrosterone, which may contribute to the development of osteoporosis.²³

Osteoporosis in Men

Osteoporosis in men was not recognized 20 years ago but is now a major public health problem owing to men's longer life spans. The epidemiology of osteoporosis in men is just now being evaluated. Fracture risk occurs in adolescence and young adulthood and then increases after the age of 70. Long bone fractures occur more commonly in young men, while hip and spine fractures are more prevalent in men older than 70 years. The increase in fractures in older men is just as significant as it is in women, but it occurs about 10 years later in life, with an age-adjusted incidence of hip fractures in men of about one-third to one-half that of women.²⁴ Elderly men who sustain hip fractures have a greater risk of dying or being permanently disabled compared with women.²⁴ Risk factors for osteoporosis in men include older age, low BMD, history of a low-trauma fracture as an adult, and a family history of osteoporotic fractures.

There are a number of secondary causes of osteoporosis in men; for instance, hypogonadism causes an increase in bone turnover and rapid bone loss as gonadal function declines with age. At this time, severe hypogonadism from androgen deprivation therapy for prostate cancer is common in elderly men. The exact role of estrogen and androgens in male skeletal health is not yet known. Although estrogen is necessary for the young male skeleton, serum estrogen levels are highly correlated with bone remodeling, BMD, and rate of BMD loss in older men; the associations are stronger than with testosterone. However, serum testosterone levels are also highly correlated with indices of bone resorption and formation. The roles of estrogen and testosterone in the male skeleton need additional investigation.²⁵ Some of the other common causes of osteoporosis in men that are not as frequent in women are alcoholism, gastrointestinal disorders including hepatic disorders, and malabsorption.²⁴

Osteoporosis in Rheumatic Diseases and Other Conditions

Recently, studies have reported significant bone loss in patients with systemic inflammatory diseases such as rheumatoid arthritis, systemic lupus erythematosus (SLE), and ankylosing spondylitis. Patients with rheumatoid arthritis experience periarticular and generalized bone loss, with an increased incidence of fractures compared with the general population.²⁶ T lymphocytes, tissue macrophages, and synovial-like fibroblasts release inflammatory cytokines (IL-1, TNF, IL-6) and inhibitory wnt signaling proteins such as dkk-1 and RANKL, which stimulate preosteoclasts in the bone marrow and synovium to actively resorb bone; in addition, osteoblast maturation is altered.^{27,28} In an animal model of inflammatory arthritis induced with collagen, animals pretreated with OPG did not have bone loss within the periarticular bone or the presence of erosions.²⁹ Additional factors that may contribute to osteoporosis in patients with rheumatic diseases include decreased mobility, glucocorticoid therapy, and systemic inflammation.³⁰ Some data,

however, show that low-dose glucocorticoid therapy in women with rheumatoid arthritis does not have adverse skeletal effects, possibly because of a decrease in disease activity in association with the suppression of inflammatory cytokines and improved physical activity and function.^{31,32} Ankylosing spondylitis is also associated with fractures and reduced bone density in the spine and proximal femur, even early in the disease.³³ Patients with SLE have a high rate of osteoporotic fractures in the presence of low to normal bone mass, suggesting that systemic inflammation alters bone turnover. Increased serum levels of TNF can reduce osteoblast maturation and increase osteoclast maturation and activity; in addition, other inflammatory factors such as oxidized low-density lipoproteins and inflammatory high-density lipoproteins can direct mesenchymal stem cells to differentiate into adipocytes instead of osteoblasts and impair bone mass.³⁴ Infiltrative processes in the marrow such as multiple myeloma, mastocytosis, and Gaucher's disease may produce osteoporosis. Patients with Gaucher's disease show an accumulation of glucocerebrosides in macrophages in the spleen, liver, and bone marrow, which causes hepatosplenomegaly, anemia, thrombocytopenia, bone infarcts and infections, fractures, and aseptic necrosis.³⁵

The immunosuppressant drug cyclophosphamide (Cytoxan) induces amenorrhea and hypogonadism, which may increase the risk of bone loss. Women who undergo premature menopause from cyclophosphamide therapy can have estrogen-deficiency bone loss in their 30s. Young women with SLE who try to preserve ovarian function while undergoing cyclophosphamide therapy by taking gonadotropin-releasing hormone agonists may also experience estrogen-deficiency bone loss. In rodent models, the immunosuppressive drug cyclosporine produces a time- and dose-dependent bone loss³⁶; in contrast, azathioprine (Imuran) and rapamycin (sirolimus) do not appear to adversely affect skeletal homeostasis.³⁷ Therapy with both cyclosporine and prednisone in transplant recipients is associated with early accelerated bone loss after the initiation of treatment and the development of osteoporosis and fractures with continued exposure.³⁸

Vitamin D deficiency may also manifest as osteopenia and fractures, but this condition is both preventable and treatable.³⁹ Vitamin D insufficiency is common in older patients and in those with SLE who do not get an adequate amount of sunlight or use potent sunscreens. Also, patients with malabsorption syndromes and liver disease can be vitamin D deficient. Unlike the situation in osteoporosis, very low vitamin D levels are often characterized by a mineralization defect and osteomalacia. Vitamin D deficiency is reported to be present in up to 50% of women with hip fractures.³⁹

Assessment of Bone Density and Osteoporotic Risk

Osteoporosis may first be diagnosed when a radiograph shows signs of demineralization or a spinal film shows evidence of compression fractures of vertebral bodies. Because an estimated 25% to 50% of bone mass must be lost to show osteopenia on radiographs, conventional radiography is an insensitive technique for diagnosing bone loss. Radiographs may demonstrate signs of secondary causes of osteoporosis

such as the presence of subperiosteal resorption in hyperparathyroidism, characteristic lytic changes or bone infarcts in Gaucher's disease, local sites of lytic destruction in malignancy, and pseudofractures in osteomalacia. Bone densitometry makes it possible to measure the amount of bone in the relevant fracture sites of the spine, forearm, and proximal femur, as well as the total body.

Techniques for evaluating bone mass include dual-energy x-ray absorptiometry (DEXA) and quantitative computed tomography (CT) scanning of the spine.^{1,2} Bone density evaluations using DEXA incorporate the attenuation of soft tissue and bone by radiographs to calculate the BMD. DEXA is both precise and safe, with a low radiation exposure. With reproducibility errors of approximately 0.6% to 1.5%, this technique can detect small changes over time.^{2,40,41} Further, newer DEXA techniques measure bone density rapidly, in 0.5 to 2.5 minutes. Quantitative CT scanning allows for the direct measurements of trabecular bone in the central region of the spine, but the procedure entails a comparatively high radiation exposure and time and precision errors are usually higher than those associated with DEXA.

Figure 101-1B and C show the BMD in a postmenopausal patient compared with that of young, healthy controls to determine whether there is reduction in BMD compared with peak bone mass (percentage of young healthy controls expressed as a t score) and with age-matched controls to assess whether BMD is diminished relative to an age-matched cohort (percentage of age-matched controls expressed as a z score). There is an inverse relationship between bone density and the gradient of risk for fracture.⁴² Prospective studies show that bone densitometry identifies patients with an increased gradient of risk for fracture. In 8134 women, a 1-standard deviation (SD) decrement in the bone density of the spine and the femoral neck compared with age-adjusted controls was associated with a 1.6- and 2.6-fold increased risk of hip fracture, respectively.⁴³ Measurement of bone density in the hip is more predictive of hip fracture than is measurement at another site. Studies show that in women older than 65 years, hip bone density is predictive of spine and hip fracture and that conventional spine density does not add to the diagnostic utility of a single hip bone density test in assessing the risk of fracture.

Although bone densitometry provides a quantitative measure of bone mass, *in vitro* studies using ultrasonography indicate that this technique also provides information about the mechanical properties of bone including both density and elasticity. These qualities are strong predictors of bone strength. Ultrasound techniques include speed-of-sound and broadband ultrasound attenuation methods; the speed-of-sound technique reflects bone density and elasticity, and broadband ultrasound attenuation is an indicator of bone density, bone structure, and composition. Approved for clinical use by the U.S. Food and Drug Administration (FDA), both ultrasound techniques have been shown to discriminate between normal and osteoporotic patients at increased fracture risk.⁴⁴ The t score parameters used by some ultrasound machines do not correspond to t score levels as measured by DEXA. Although ultrasonography is a radiation-free technique that may provide information about the risk of fracture and bone quality, the

reproducibility of this technique and the measurement sites of mainly cortical bone or low-weight-bearing locations may make it unsuitable for monitoring small changes in bone over time. Therefore ultrasound measurements cannot reliably be used to monitor response to osteoporosis therapies. Further data are necessary to validate the clinical utility of ultrasonography.

On the basis of the guidelines of the Scientific Advisory Board of the National Osteoporosis Foundation, bone densitometry is useful in determining which patients might benefit from therapy to protect the skeleton including patients who have a deficiency of gonadal hormones (postmenopausal women younger than 65 years with one or more risk factors or older than 65 years regardless of risk factors), postmenopausal fracture, evidence of osteopenia or a vertebral abnormality on radiographs, hyperparathyroidism, or exposure to supraphysiologic doses of glucocorticoids (Table 101-3). Bone densitometry is also used to decide when to commence therapy for osteoporosis and to assess the clinical response to therapeutic interventions.⁴⁰ Screening normal premenopausal women is not cost-effective.

The World Health Organization (WHO) has published criteria for osteoporosis on the basis of bone density^{1,45}:

1. Normal bone density if the t score is greater than -1 .
2. Osteopenia (low bone mass) is defined as a bone density measurement between 1 and 2.5 SD below the young-adult mean (t score between -1 and -2.5).
3. Osteoporosis is defined as a bone density measurement less than 2.5 SD below that of young, healthy controls (t score < -2.5).

The National Osteoporosis Foundation recommends treatment for all individuals who have a lumbar spine, hip, or femoral neck t score of -2.5 or lower. However, for individuals who have a bone density between -1 and -2.5 the National Osteoporosis Foundation recommends performing a Fracture Risk Assessment or FRAX using a computer program that incorporates clinical risk factors for osteoporosis with and without femoral neck BMD. FRAX also provides a 10-year risk of a hip fracture or a major osteoporotic fracture (hip, proximal humerus, and wrist). The clinical risk factors included in the FRAX program include age, weight, height, history of a fracture as an adult, parental history of a hip fracture, current glucocorticoid use, secondary cause of osteoporosis, alcohol intake of more than two drinks a day, and current smoker.^{45,46} These risk factors are added to femoral neck t score for the 10-year fracture risk. In the

Table 101-3 Indications for Bone Densitometry

All postmenopausal women < 65 yr who have one or more additional risk factors for osteoporosis (besides menopause)
All women > 65 yr regardless of additional risk factors
To document reduced bone density in patients with vertebral abnormalities or osteopenia on radiographs
Estrogen-deficient women at risk for low bone density who are considering use of estrogen or an alternative therapy, if bone density would influence the decision
Women who have been on estrogen replacement therapy for prolonged periods or to monitor the efficacy of a therapeutic intervention or interventions for osteoporosis
To diagnose low bone mass in glucocorticoid-treated individuals
To document low bone density in patients with asymptomatic primary or secondary hyperparathyroidism

United States, a 10-year risk of hip fracture of 3% or more or a major osteoporotic fracture of 20% or more is the threshold to recommend treatment. However, the fracture risk threshold for treatment is individualized by treatment, so it is important to enter the country in which you are practicing medicine. FRAX has advantages that include easily determined risk factors, global validation, application in specific regions or nations, and scores that pertain to both men and women. However, there are a number of limitations including that it can lead to underestimates or overestimates of fracture risk in some patients, because it does not include all known risk factors and some risk factors are superficial (e.g., glucocorticoid use is the question, but dose is not evaluated). Such known or suspected risk factors that contribute to fracture risk but are not included in the FRAX algorithm include immobilization, epilepsy, chronic obstructive pulmonary disease, diabetes, and depression. Lastly, the FRAX score is calibrated only for untreated patients and results can be misleading for patients already taking pharmacologic therapy.^{45,46}

Markers of Bone Turnover

The development of sensitive biochemical markers of bone turnover makes it possible to analyze changes in bone formation and resorption at a given point in time and obtain additional information about a patient's risk of bone loss and fracture. Only three bone formation markers are currently available. Osteocalcin, a noncollagenous matrix protein in bone, is produced exclusively by osteoblasts; it correlates with histomorphometric bone measurements. In most conditions, bone resorption and formation are tightly coupled and osteocalcin levels reflect bone turnover. The other markers of bone formation are bone-specific alkaline phosphatase (BSAP), an enzyme that is activated as osteoblasts mature, and amino-terminal propeptide of type I procollagen, a protein whose synthesis is high in maturing osteoblasts.⁴⁷

Sensitive indicators of bone resorption derived from the degradation of mature collagen include the urine and serum markers of type I collagen cross-links including amino-terminal telopeptide of type I collagen (N telopeptides, or NTX) or carboxy-terminal telopeptide of type I collagen (C telopeptides, or CTX). Urinary pyridinoline cross-link, NTX, and CTX levels correlate with histomorphometric determinations of bone resorption; these biomarkers increase with menopause and are high in patients with a variety of disorders characterized by accelerated bone turnover including Paget's disease, osteoporosis, and rheumatoid arthritis.^{48,49} Urinary excretion of N telopeptides is inversely related to total hip and spinal bone density and, according to some studies, may be a more specific index of bone resorption than urinary pyridinoline levels.⁵⁰ Small prospective studies have found high turnover markers, and low BMD has been associated with incident fracture risk but these studies have not been replicated in larger studies.^{51,52} In clinical studies, antiresorptive agents such as estrogen, bisphosphonates, and inhibitor of RANKL induce a significant decrease (30% to 80%) first in markers of resorption and then in bone formation markers, often within 3 to 6 months. Resorption markers decrease before formation markers and correlate with either maintenance of or increase

in BMD. A significant change in bone markers can be observed within months of antiresorptive therapy, before there are changes in BMD.⁵² Both bone formation and resorption marker changes over 6 to 12 months have been found to predict future fracture risk. In a study of alendronate to reduce osteoporotic fractures, patients who had more than a 30% reduction in bone alkaline phosphatase had the greatest reduction in risk for new vertebral and nonvertebral fractures. Interestingly, studies have found that reductions in markers of bone turnover, either resorption or formation markers, are associated with a reduction in fracture risk. However, long-term, prospective studies of large numbers of women are necessary to determine whether selective biochemical markers of bone turnover can predict changes in BMD or fracture risk and whether these tests should be used in standard clinical practice.

Most bone turnover marker data are derived from large studies of antiresorptive agents. However, a bone-building anabolic agent, PTH, has been approved for the treatment of osteoporosis. PTH's action is to stimulate osteoblast activity; therefore osteocalcin and other markers of bone formation increase rapidly, within a few weeks of the initiation of treatment. However, activation of the osteoblast over time results in RANKL production, which stimulates osteoclast activity. With continued PTH treatment, markers of osteoclast activity also increase, reaching levels equal to those of formation markers. Because the overall result is an increase in bone mass, the bone turnover markers during PTH therapy reflect significant bone remodeling on both trabecular and cortical bone surfaces. A few small studies have found that increases in both bone formation and resorption markers predict an increase in bone mass with PTH treatment.⁵³⁻⁵⁵

Evaluation for Secondary Bone Loss

The workup for osteoporosis is directed toward excluding secondary causes of bone loss and includes a determination of serum calcium, phosphorus, supersensitive thyroid-stimulating hormone, 25-hydroxyvitamin D (25-OHD), and intact PTH, as well as urine calcium and creatinine levels. Also, a complete blood cell count, alkaline phosphatase and liver function tests, erythrocyte sedimentation rate (in some cases), and serum and urine protein electrophoresis for patients older than 50 years may be necessary (Table 101-4). In men, additional testing for secondary causes of osteoporosis includes serum testosterone and luteinizing hormone.

Further tests to rule out neoplastic or endocrinologic disorders and a bone biopsy (a decalcified bone specimen is obtained after a double tetracycline label with two different fluorescent labels) should be considered in certain patients with progressive bone loss and in those in whom osteoporosis is unlikely. Identification and appropriate therapy for underlying secondary causes of osteoporosis are important. For example, treatment of vitamin D deficiency is best accomplished with vitamin D supplements. Parathyroidectomy in patients with hyperparathyroidism characterized by hypercalcemia, hypercalciuria, nephrolithiasis, age younger than 50 years, or low cortical BMD (z score ≤ 2) was associated with a large (4% to 12.8%) increase in bone density over 4 years.⁵⁶ Bone density was, however, stable for up to

6 years in patients with mild hyperparathyroidism.⁵⁷ In addition, treatment of hyperthyroidism, hypercortisolism, and a variety of other disorders that may cause osteoporosis can produce increments in bone mass. Reduction in the systemic inflammation associated with rheumatic diseases such as TNF blocking agents for rheumatoid arthritis or ankylosing spondylitis or glucocorticoid-sparing agents for SLE (e.g., azathioprine [Imuran], mycophenolate mofetil [CellCept]) can also produce increments in bone mass.

Treatment

Calcium

The goals of therapy for osteoporosis are to reduce bone resorption and enhance bone formation, if possible. Bone loss occurs when the calcium intake and absorption are insufficient to balance the daily calcium losses. Prospective data show that calcium stabilizes bone mass.⁵⁸

Table 101-5 shows the current recommendations for optimal calcium intake for women and men from the 1997 report of the Institute of Medicine to the National Academy of Sciences.⁵⁹ In the absence of kidney stones or an underlying disorder of calcium metabolism, these calcium intakes are safe. To prevent negative calcium balance, premenopausal women require 1000 mg and postmenopausal women 1200 mg of total elemental calcium daily.⁶⁰ Children have increasing calcium requirements during adolescence, and data show increased bone accretion with increased calcium intake in prepubescent and pubertal children. Calcium carbonate contains 40% elemental calcium and should be taken with meals because of poor absorption in achlorhydric patients in the absence of food. Calcium citrate, which contains 24% elemental calcium, has better bioavailability and is more readily absorbed.⁶¹ It is also absorbed well on an empty stomach in patients with achlorhydria. Recent studies underscore the fact that only recommended daily allowances of calcium and vitamin D are useful for bone health in postmenopausal women and elderly men. Additional supplementation over the recommended daily allowance has resulted in reports of increased cardiovascular disease.^{61a-61c}

Estrogen

Hormone replacement therapy (HRT) was once the mainstay of treatment in osteoporosis because estrogen inhibits bone resorption, produces a small rise in bone density, and reduces the risk of fracture by approximately 50% in retrospective observational studies. Cardiovascular disease is the leading cause of death in postmenopausal women. Previous data from longitudinal observational studies suggested that estrogen replacement had a beneficial effect on reducing primary and secondary cardiac events in postmenopausal women. However, in 1998, data from the 4-year Heart and Estrogen/Progestin Replacement Study were published.⁶² In this study, 2763 postmenopausal women with a previous history of heart disease were randomized to receive estrogen (0.625 mg) plus progestin (2.5 mg) or placebo alone. Results showed no reduction in the overall rate of coronary heart disease or cardiac events in the treatment group; in fact, an early increase in risk for cardiac events was noted, possibly related to increased coagulability.⁶³

In addition, a large, multicenter, longitudinal study by the Women's Health Initiative (WHI)—in which 162,000 women aged 50 to 79 years were randomized into a placebo group, an HRT group (if the uterus was intact), or an estrogen-only group (if the uterus was absent)—was terminated early due to an increased risk of breast and cardiovascular events. The research goals for the WHI study were to determine the effects of HRT, diet modification, and calcium and vitamin D supplements on heart disease, osteoporosis, and colorectal cancer risk. After a mean follow-up of 5.3 years in an 8.5-year study, the HRT group had an increased risk of seven more cardiac events per 10,000 women taking the drug for a year, eight more invasive breast cancers, eight more strokes, and eight more pulmonary emboli, but six fewer colorectal cancers and five fewer hip fractures.⁶⁴

At this time, the general recommendation is that HRT should be used only for vasomotor symptoms that occur at the time of menopause. When these symptoms abate, it is recommended that estrogen replacement (combined estrogen and progestin for women with an intact uterus) be stopped because the perceived cardiovascular benefits have

Table 101-5 Calcium Requirements Recommended by the National Academy of Sciences (USA)

Age Group	Optimal Daily Calcium Intake (mg)
Infants	
Birth-6 mo	400
6 mo-1 yr	600
Children 1-8 yr	500-800
Adolescents 9-18 yr	
9-10 yr	800-1200
11-18 yr	1200-1500
Pregnant and nursing females	1300
Men and women	
19-50 yr	1000
>50 yr (\pm hormone replacement therapy)	1200-1500

Modified from Atkinson SA, Abrams SA, Dawson-Hughes B, et al: Calcium. In Young V, editor: *Dietary reference intake for calcium, phosphorus, magnesium, vitamin D and fluoride*, Washington, DC, 1997, National Academy Press, pp 91-143.

not been substantiated, and the cardiovascular disease and breast cancer risk make the benefit-to-risk ratio unacceptable for most women. It is important to acknowledge that the estrogen-only arm of the WHI study in women without a uterus did not show an increased risk of heart disease or breast cancer.

If a woman and her physician decide that she is going to take HRT or estrogen alone for vasomotor symptoms, in those with an increased risk of coagulability, transdermal estrogen replacement should be used.

Selective Estrogen Receptor Modulators

The ideal estrogen replacement therapy would confer the beneficial effects of estrogen on bone and cardiovascular disease without increasing the risk of breast or uterine cancer. Selective estrogen receptor modulators (SERMs) are a nonsteroidal class of drugs that bind to the estrogen receptor and differ from one another in their actions on estrogen-responsive tissues, acting selectively as agonists or antagonists. Tamoxifen, the first available SERM, is an estrogen antagonist that binds to the estrogen receptor and also has estrogen-agonist effects on bone, lipids, clotting factors, and endometrium. Tamoxifen therapy in women with breast cancer produced a small increase in bone density of the spine over 2 years, with no effect on radial bone density, in association with reductions in both low-density lipoprotein and total cholesterol.⁶⁵ The Breast Cancer Prevention Trial studied 13,388 women at increased risk for breast cancer, comparing treatment with tamoxifen (20 mg daily) to placebo for 5 years.⁶⁶ Tamoxifen reduced the risk of invasive and noninvasive breast cancer by 50%, and a decreased risk of fracture was observed as well: 45% reduction at the hip and 29% at the spine. An increased incidence of low-grade endometrial cancer was noted, but there was no change in the risk of ischemic heart disease.⁶⁶

Raloxifene,⁶⁷ now FDA approved for the prevention and treatment of osteoporosis, is a SERM that acts as an estrogen agonist on bone, with antagonist effects on the breast and uterus.⁶⁸ Raloxifene (60 mg/day over a 2-year study period) increased BMD in the lumbar spine by 2.4%, in the total hip by 2.4%, and in the total body by 2%, with a reduction in fracture risk at 2 years similar to that seen with estrogen or alendronate (5 mg) treatment. Over the 2-year study period, raloxifene produced a significant reduction in vertebral fractures: Fractures were present in 1.6% of raloxifene-treated women, compared with 2.9% of those in the placebo group; fractures recurred in 7.6% of treated women with a previous fracture, compared with 14.3% of those in the placebo group.⁶⁹ Endometrial thickness is not increased by raloxifene, but menopausal symptoms may be made worse. Raloxifene has been shown to decrease low-density lipoprotein cholesterol by 12%, with a nonsignificant increase in high-density lipoprotein cholesterol; cardiovascular protection has not yet been determined.⁷⁰ However, raloxifene, unlike estrogen, does not affect C-reactive protein, which is associated with a risk of cardiovascular disease.^{71,72} Raloxifene also decreased the incidence of breast cancer by 76% in patients enrolled in a clinical study of osteoporosis, with breast cancer incidence studied as a secondary endpoint.⁶⁷ A study that evaluated the effects of raloxifene on cardiovascular disease found no

effect.⁷³ One study compared tamoxifen and raloxifene, and another study evaluated raloxifene versus placebo, in the prevention of breast cancer. The first study reported that both tamoxifen and raloxifene reduced the risk of developing breast cancer, and the second found that raloxifene reduced the risk of estrogen receptor–positive breast cancer compared with placebo in postmenopausal women.^{74,75} At this time, there is little information on the use of raloxifene in men, so it is not recommended for male patients.

Testosterone

Men with osteoporosis, hypogonadism, and symptoms of low libido may benefit from testosterone replacement therapy. This can be administered as testosterone cypionate or enanthate (50 to 400 mg intramuscularly every 2 to 4 weeks) or as a transdermal testosterone replacement patch that is applied to the scrotal area (Testoderm, 4 to 6 mg/day) or elsewhere (Androderm, 2.5 or 5 mg/day).⁷⁶ Most studies find that bone mass increases with testosterone replacement when levels of testosterone were low at the initiation of therapy.

Calcitonin

Calcitonin, a 32-amino acid peptide synthesized by the C cells of the thyroid gland, is a potent inhibitor of osteoclast-mediated bone resorption. Although human and salmon calcitonin are commercially available, salmon calcitonin is most commonly used because of its greater potency. On the basis of data showing an increase in total body calcium, parenteral calcitonin was approved by the FDA for the treatment of osteoporosis in 1984, and calcitonin in a nasal spray was approved for the treatment of postmenopausal osteoporosis in 1995. Parenteral calcitonin (100 IU subcutaneously or intramuscularly three times a week or daily) can maintain bone density or produce a small increase in bone mass in the spine and, in some instances, the forearm, particularly in patients with a high bone turnover.⁷⁷ Nasal spray calcitonin is absorbed through the nasal mucosa and is approximately 40% as potent as the parenterally administered drug (e.g., 50 to 100 IU of injectable calcitonin is comparable with 200 IU of nasal spray calcitonin).⁷⁸ In osteoporotic women more than 5 years past menopause, nasal calcitonin (200 IU/day) increases spinal bone density 2% to 3% compared with placebo, with no effect on proximal femur bone mass; higher doses are necessary in the early menopausal period.^{78,79} Nasal spray calcitonin therapy in patients with osteoporosis is associated with a 36% reduction in vertebral fractures over 5 years.⁷⁹

The adverse effects of parenteral calcitonin include nausea, flushing, and local irritation at the injection site. Calcitonin given intranasally is well tolerated, with rhinitis and nasal symptoms such as dryness and crusting being potential side effects. Patients treated with parenteral or intranasal calcitonin may also obtain a beneficial analgesic response in the presence of osteoporotic fractures.

Bisphosphonates

Bisphosphonates are analogues of pyrophosphate, with a P-C-P rather than a P-O-P core; they are absorbed by the

Table 101-6 Inhibition of Metaphyseal Bone Resorption in Vivo by Bisphosphonates

Chemical Modification	Examples	Antiresorptive Potency
First generation: short alkyl or halide side chain	Etidronate	1
	Clodronate	10
Second generation: NH ₂ -terminal group	Tiludronate*	10
	Pamidronate	100
	Alendronate	100-1000
Third generation: cyclic side chain	Risedronate	1000-10,000
	Ibandronate	1000-10,000
	Zoledronate	10,000

*Tiludronate has a cyclic side chain, not an NH₂-terminal group, but it is generally classified as a second-generation compound on the basis of its time of development and potency.

Modified from Watts NB: Treatment of osteoporosis with bisphosphonates [review], *Endocrinol Metab Clin North Am* 27:419-439, 1998.

hydroxyapatite of bone and suppress bone resorption. Modification of the side chains can result in the development of a variety of compounds with differing abilities to inhibit bone resorption (Table 101-6). Some bisphosphonates are administered intermittently because of a long skeletal half-life and prolonged retention in bone. These compounds must be taken on an empty stomach because gastrointestinal absorption is less than 10%.

Bisphosphonates have been used for the treatment of patients with Paget's disease of bone, hypercalcemia of malignancy, and osteoporosis and for the prevention and treatment of glucocorticoid-induced osteoporosis. Etidronate (Didronel) administered intermittently (400 mg/day for 2 weeks in 3-month cycles) produced approximately 5% increase in bone density of the spine and a 50% reduction in vertebral fractures at 2 years. Longer follow-up did not reveal a significant reduction in vertebral fractures compared with baseline, except in a post hoc analysis of patients with three or more fractures and low bone density.⁸⁰ Etidronate is not approved by the FDA for the treatment of osteoporosis.

Alendronate (Fosamax) is FDA approved for the prevention and treatment of osteoporosis. Data in postmenopausal women with bone density at least 2.5 SD below peak bone mass show that alendronate (10 mg/day) compared with placebo produces an 8.8% and 7.8% increase in bone density in the spine and femoral trochanter, respectively, and a 5.9% increase in the femoral neck after 3 years of therapy⁸¹; there are smaller rises (2.3% to 4.4%) in bone density in the spine and proximal femur in women within 0.5 to 3 years of menopause. Fosamax treatment in women with osteoporosis (t score < 2.5) yields a significant reduction in spine and hip fractures compared with the placebo-treated patients.⁸² Treatment with alendronate (5 mg/day over 2 years) increased BMD in the lumbar spine by 2.9% and in the hip by 1.3%; in contrast, estrogen-progestin therapy increased BMD in these locations by 4% and 1.8%, respectively.⁸³ Alendronate did not reduce the incidence of clinical fractures in women who had low bone mass but not osteoporosis, although longer studies may be necessary.⁸⁴ Alendronate treatment is also effective in increasing bone mass in the spine, hip, and total body and helps prevent vertebral fractures and height loss in men with osteoporosis.⁸⁵ Adverse effects of bisphosphonates include

gastrointestinal symptoms such as stomach pain and esophagitis (caution is advised in patients with active symptoms or a history of ulcer disease), myalgias and arthralgias, and, rarely, osteonecrosis of the jaw, and subtrochanteric fractures with long-term use. A once-a-week preparation of alendronate (70 mg) is the most commonly used dose for the treatment of osteoporosis.⁸⁶ This preparation increased spinal and hip bone mass similarly to alendronate 10 mg/day over a 2-year study period.

Risedronate, another oral bisphosphonate, administered at a dose of 5 mg/day increased bone mass and reduced the risk of new vertebral fractures 50% better than placebo.⁸⁷⁻⁸⁹ Another study performed to assess the effect of risedronate on hip fractures found that women with osteoporosis (defined by a femoral neck t score of ≤ -4.0) had a significant reduction in the risk of hip fracture.⁹⁰ Risedronate has been approved for the prevention and treatment of osteoporosis (35 mg once a week)⁹¹ and for the treatment of Paget's disease (30 mg/day for 2 months, with retreatment if relapse occurs after 2 months).⁹² Studies show that risedronate may be well tolerated even in patients with mild gastrointestinal symptoms. Bisphosphonates may also reduce bone pain.

Ibandronate (Boniva), another aminobisphosphonate, is approved for the treatment and prevention of postmenopausal osteoporosis. In phase III studies of ibandronate (2.5 mg/day) versus placebo in postmenopausal women with osteoporosis, incident vertebral fractures were reduced about 50%. Another study compared ibandronate 150 mg once a month to the daily 2.5-mg dose and found similar gains in lumbar spine and hip BMD. The FDA approved ibandronate 150 mg/month for the treatment of osteoporosis on the basis of this bridging study.⁹³ Recently, intravenous ibandronate in a dose of 3 mg every 3 months was found to be similar to ibandronate 2.5 mg/day in terms of increasing lumbar spine and hip BMD, and the FDA has approved intravenous ibandronate for this indication. There are no data on hip fractures for this compound.⁹⁴

Zoledronic acid (Reclast) is approved for the treatment and prevention of postmenopausal osteoporosis.⁹⁵ In phase III studies in postmenopausal women with osteoporosis treated with zoledronic acid, 5 mg once a year by intravenous infusion, the risk of incident vertebral fractures was reduced by 68%, hip fractures by 40%, and other major osteoporotic fractures by 20% compared with the placebo-treated subjects.⁹⁵ Another phase III study of patients who had suffered a hip fracture were randomized to either zoledronic acid 5 mg once a year of placebo and after 3 years found that incident osteoporotic fractures were significantly less in zoledronic-treated patients and the mortality was lowered compared with the placebo-treated patients.⁹⁶ Side effects of zoledronic acid include arthralgias and myalgias; however, these adverse events tend to be less frequent with subsequent infusions. Patients undergoing zoledronic acid treatment should have both serum calcium and 25-OHD levels monitored and replaced to normal levels before treatment. Zoledronic acid has been approved for the treatment and prevention of postmenopausal osteoporosis (5 mg once a year), osteoporosis in men (5 mg a year), prevention and treatment of glucocorticoid-induced osteoporosis (5 mg a year), and Paget's disease. Zoledronic acid at a dose of 4 mg intravenously every 4 weeks is currently approved for the

prevention and treatment of bone metastases in patients with breast cancer and multiple myeloma.

RANK Ligand Inhibitor

Denosumab (Prolia) is a monoclonal antibody that is directed against RANKL and is approved for the treatment of postmenopausal osteoporosis. In phase III studies in postmenopausal women with osteoporosis treated with denosumab (60 mg subcutaneously every 6 months) for 36 months or 3 years, the incidence of vertebral fractures was reduced by 68%, hip fractures by 40%, and major osteoporotic fractures by 20%.⁹⁷ The medication is well tolerated, but adverse events of skin infection requiring hospitalization were higher in denosumab-treated subjects than placebo-treated subjects. Denosumab is a potent inhibitor of bone resorption with suppression of a marker of osteoclast activity.

CTX-1 is suppressed to nearly 90% a few weeks after each injection; however, the suppression of bone turnover is transient and bone turnover and bone density return to baseline levels rapidly if the injections of denosumab are discontinued. Postmenopausal women with low bone mass who were treated with alendronate 70 mg once a week and then switched to denosumab (60 mg every 6 months) had a significant gain of BMD compared with subjects continued on alendronate.⁹⁸ Before treatment with denosumab, serum calcium and 25-OHD should be checked and replaced if needed up to normal levels.

Parathyroid Hormone

Small randomized studies have determined that the 1-34 fragment of the PTH protein can significantly increase bone mass in the spine, with small losses or no gain at the skeletal sites rich in cortical bone.^{99,99a} In 2001 a recombinant human PTH (rhPTH) composed of the 34 amino acids from the amino-terminal end of the hormone, known as *Fortéo*, was approved for the treatment of postmenopausal osteoporosis. In a large international, multicenter study, osteoporotic women with fracture were randomized to receive rhPTH 20 µg/day, 40 µg/day, or placebo for an average of 21 months. Lumbar spine bone mass increased between 9% and 13% in the rhPTH-treated subjects compared with the placebo-treated ones; hip bone mass also increased slightly. Most important, the risk of new vertebral fractures was reduced nearly 70% in both sets of rhPTH-treated subjects, and nonvertebral low-trauma fractures were reduced nearly 50% compared with placebo-treated patients.¹⁰⁰ This study was initially supposed to continue for 3 years; however, it was stopped at approximately 21 months because of preclinical evidence of malignant bone tumors in animal models. Additional studies of osteoporosis in men treated with rhPTH 1-34 have reported significant gains in bone mass.¹⁰⁰ *Fortéo* is given as a daily injection. Individuals using this medication may experience headache, nausea, and flushing with initiation of treatment, but these side effects generally become less severe after a few weeks.

A number of recent studies have evaluated whether rhPTH 1-34 or rhPTH 1-84 is more effective in combination with an antiresorptive agent (either bisphosphonates or raloxifene) than rhPTH alone in increasing BMD and

reducing fractures.^{101,102} Interestingly, two studies found that the combination of PTH and alendronate was less effective in stimulating bone gain at the lumbar spine in both osteopenic women and men over 1 to 1.5 years.^{101,102} PTH stimulates new bone formation, increases bone mass, and reduces new vertebral and nonvertebral fractures, but when the medication is discontinued, the bone gained is rapidly lost. Black and colleagues¹⁰³ performed a study in which patients were given PTH for 1 year, followed by 1 year of alendronate treatment. Interestingly, the BMD gain after 1 year of PTH was about 6%; when followed by alendronate, nearly 6% BMD was gained at the spine. These data suggest that although PTH is an effective monotherapy for increasing bone mass, especially in the spine, the gain in BMD should be maintained with a potent antiresorptive agent for a number of years. Recent data from Deal and colleagues¹⁰⁴ indicate that lumbar spine BMD gained after PTH therapy is maintained with raloxifene treatment.

PTH is the first bone anabolic agent approved for the treatment of osteoporosis. Patients give themselves a subcutaneous injection daily for 18 to 24 months. Other routes of administration are now being studied including an intranasal route and a skin patch.

Vitamin D

Physiologic doses of vitamin D are important to ensure normal bone mineralization. Individuals 50 years of age and older should take at least 600 to 1000 IU of vitamin D daily as a multivitamin or combined with a calcium supplement. Hypovitaminosis D is common in the elderly population, with one study demonstrating that 57% of patients in a general medical ward were vitamin D deficient.¹⁰⁵ Low vitamin D levels increase the risk of bone loss and fracture. LeBoff and colleagues³⁹ found that 50% of patients admitted with acute femur fractures had vitamin D deficiency (25-OHD level <12 ng/mL), and 36.7% had secondary hyperparathyroidism. Data show seasonal variations in vitamin D levels; low 25-OHD levels during the winter and spring are associated with decreases in bone density. The importance of vitamin D to skeletal health was shown when elderly women in a nursing home treated with only 800 IU/day of vitamin D had a 40% reduction in incident hip fractures over 18 months, compared with placebo-controlled subjects.¹⁰⁶ Although this dramatic effect on fractures in an elderly population may represent a correction of vitamin D insufficiency, this study underscores that adequate vitamin D replacement can effectively diminish fractures in older individuals. Insufficient calcium and low 25-OHD levels are common in ambulatory patients and should be identified and treated before antiresorptive or other therapies for osteoporosis are initiated.

Although 200 IU of vitamin D prevents bone loss in the spine, data show that a higher daily intake (800 IU) is necessary to diminish bone loss in the hip during the winter and spring. Daily treatment with 700 IU of cholecalciferol and 500 mg of calcium carbonate reduced the rate of bone loss significantly in the femoral neck, spine, and total body and decreased the incidence of nonvertebral fractures by 50%.¹⁰⁷ Therefore to maintain skeletal health, patients require a vitamin D intake that results in a serum 25-OHD level of at least 30 ng/mL. To achieve this level

in patients who do not receive regular sunlight, the daily intake of vitamin D needs to be higher. Replacement with 1,25-dihydroxyvitamin D ($1,25[\text{OH}]_2\text{D}$) is not recommended because hypercalcemia and hypercalciuria are common and require regular and costly monitoring.

Preventive Measures

Because bone loss is not completely reversible with existing therapies, prevention is essential for optimizing skeletal health. Strategies directed at increasing peak bone mass, reducing risk factors for bone loss (e.g., hypogonadism, decreased body fat, cigarette smoking, inactivity, excessive alcohol intake), and reversing the secondary causes of osteoporosis may prevent bone loss. Patients should be advised to consume adequate vitamin D and calcium and participate in a regular weight-bearing exercise program. Weight-bearing exercise increases muscle strength and may stabilize or modestly increase bone density. Emerging data show that increased calcium intake and exercise can add to bone accretion during adolescence and that interventions such as vitamin D and calcium supplementation can reduce fractures in older patients. Thus it is highly recommended that preventive strategies or therapies be instituted at any age to diminish the risk of fractures, which rises exponentially with age.

GLUCOCORTICOID-INDUCED OSTEOPOROSIS

Bone loss is a common sequela of therapy with glucocorticoids,¹⁰⁸ and glucocorticoid use increases the risk of fractures in patients with rheumatic diseases.¹⁹ The severity of the bone loss in glucocorticoid-treated patients varies, with an approximately 3% to 20% decrease in bone density over 1 to 2 years. Glucocorticoid therapy is associated with increased fractures of the ribs and vertebrae, sites that contain predominantly trabecular bone, and it triples the risk of hip fracture in one-third of patients after 5 to 10 years of treatment.^{109,110} In adults, alternate-day glucocorticoid therapy does not prevent bone loss. In patients with rheumatic diseases, concerns over the development of glucocorticoid-induced osteoporosis often limit the dose and duration of glucocorticoid therapy.

The lowest possible glucocorticoid dose should be used, along with general preventive strategies such as a regular weight-bearing exercise program, adequate calcium and vitamin D intake, and reduction of other risk factors that might contribute to the development of osteoporosis. However, data show that even patients on prednisone 5 mg/day have accelerated bone loss compared with controls. General prophylactic measures to prevent glucocorticoid-induced osteoporosis are shown in Table 101-7. Intestinal calcium absorption is impaired in glucocorticoid-treated patients, and early studies showed that this could be offset with vitamin D (40 to 100 $\mu\text{g}/\text{day}$ two to three times a week) or 25-OHD, which produced an increase in bone density of the forearm. However, the administration of supraphysiologic doses of vitamin D requires careful monitoring of the serum and urinary calcium concentrations in patients at high risk for bone loss (with a normal urinary calcium

Table 101-7 Recommendations for Prevention and Treatment of Glucocorticoid-Induced Osteoporosis

Prevention
Patients starting GC therapy at a dose equivalent to prednisone ≥ 5 mg/day for 3 mo or longer should: Modify risk factors for osteoporosis (stop smoking, decrease excessive alcohol consumption) Start regular weight-bearing physical exercise Initiate intake of calcium (total 1500 mg/day) and vitamin D (400-800 IU/day) Consider BMD testing to predict risk of fracture and bone loss Initiate bisphosphonate therapy (alendronate 5 mg/day or 35 mg/wk, or risedronate 5 mg/day or 35 mg/wk)
Treatment
Patients on long-term GC therapy should be tested for osteoporosis using BMD measurement. If the T-score is < -1 , consider: Risk factor modification including reducing risk of falls Regular weight-bearing physical exercises Calcium and vitamin D supplementation Replacement of gonadal steroids, if deficient Bisphosphonate therapy (alendronate 10 mg/day or 70 mg/wk, or risedronate 5 mg/day or 35 mg/wk); if bisphosphonates are contraindicated or not tolerated, consider calcitonin as second-line agent, intravenous bisphosphonate (pamidronate or zoledronate), or parathyroid hormone 1-34 Repeat BMD measurement annually or biannually

BMD, bone mineral density; GC, glucocorticoid.

Modified from Recommendations for the prevention and treatment of glucocorticoid-induced osteoporosis: 2001 update, *Arthritis Rheum* 44:1496-1503, 2001.

level and no history of nephrolithiasis). An alternative approach in patients at risk for osteoporosis and receiving long-term glucocorticoid therapy is to raise the 25-OHD level into the upper-normal range (>30 ng/mL) to ensure adequate intestinal calcium absorption. This can usually be accomplished by administering vitamin D at 800 IU/day.

Because of the enhanced bone resorption in patients treated with glucocorticoids, investigators have examined the effects of inhibitors of bone resorption. The use of bisphosphonates in patients receiving chronic glucocorticoid therapy is beneficial for both the prevention and treatment of osteoporosis. The use of alendronate 5 or 10 mg/day for 1 year in patients receiving glucocorticoid therapy increased lumbar spine BMD by 2.1% and 2.9%, respectively, and increased femoral neck BMD by 1.2% and 1%, respectively ($P < .001$).¹¹⁰ After 1 year of treatment, there was an insignificant reduction in new vertebral fractures, but after 2 years of treatment, there was a nearly 40% reduction in new vertebral fracture risk. Risedronate 5 mg/day was also effective in the prevention and treatment of glucocorticoid-induced bone loss.¹¹¹ Recent studies of zoledronic acid (5 mg IV/year) versus risedronate (5 mg/day) and teriparatide (20 $\mu\text{g}/\text{day}$) versus alendronate (10 mg/day) for 18 months indicated that both zoledronic acid and teriparatide improved bone mass more than the comparator, and teriparatide-treated subjects had a significant vertebral fracture risk reduction^{112,113} in glucocorticoid-treated patients. Combination studies of rhPTH 1-34 with HRT were also found to be more effective than HRT alone in glucocorticoid-induced osteoporosis.¹¹⁴ No difference between treatments in fracture data was observed; however, quantitative CT of the lumbar spine, a measure of only

trabecular bone, found a nearly 35% increase in PTH-treated patients compared with the estrogen-only group after 12 months of therapy.¹¹⁵

Men on glucocorticoids can have a lowering of testosterone levels.¹¹⁶ They are generally asymptomatic, but if men on glucocorticoids have evidence of low serum testosterone levels and symptoms of low libido, they can be safely treated with testosterone. Bone mass increases have been observed in men with low testosterone levels on glucocorticoids who were treated with testosterone.¹¹⁷ However, because of the risks associated with testosterone treatment, it is more prudent to treat these patients with a bisphosphonate medication.

To prevent bone loss in patients with pulmonary diseases requiring glucocorticoid therapy, treatment with inhaled glucocorticoids has been studied.¹¹⁸ Inhaled glucocorticoids appear to uncouple bone turnover and increase bone loss; however, this is dose dependent. Less than 800 µg/day of inhaled budesonide dipropionate does not increase the risk of osteoporosis, but more than 800 µg/day does. New inhaled steroids are more potent than older ones; for instance, Advair 200 µg/day is equivalent to nearly 5 mg/day of prednisone.¹¹⁹ Therefore patients on chronic steroid inhalers should be screened for bone loss. Because patients receiving glucocorticoids may lose a dramatic amount of bone, it is important to monitor the efficacy of a treatment intervention, assess the need for further diagnostic evaluation for other causes of bone loss, and consider alternative treatment strategies if a given therapy is ineffective in preventing bone loss or fractures. In patients at increased risk of fracture, therapy with a potent bisphosphonate is highly recommended to slow bone loss and the rate of new fractures. Alendronate, risedronate, and zoledronic acid are available for use, and future studies of more potent bisphosphonates and PTH are expected.¹²⁰⁻¹²²

OSTEOMALACIA

Osteomalacia is characterized by impaired mineralization of bone matrix. Calcium, phosphate, and vitamin D are necessary for the mineralization of bone. Normally, there is a steep inverse relationship between the serum calcium and PTH concentrations. A small decrease in the serum calcium concentration leads to a rise in PTH release, which promotes distal renal calcium reabsorption, proximal tubulorenal phosphorus excretion, and resorption of calcium from bone. Vitamin D is produced in the skin in the presence of ultraviolet light or absorbed in the intestine from dietary or supplemental sources. Activation of vitamin D to 25-OHD occurs in the liver and to 1,25(OH)₂D in the proximal tubules of the kidney. PTH, hypocalcemia, and hypophosphatemia stimulate the renal 1-hydroxylase enzyme that converts 25-OHD to 1,25(OH)₂D, which in turn indirectly enhances intestinal calcium absorption.¹²³

Osteomalacia results from reduced availability of calcium or phosphate for incorporation into the hydroxyapatite of bone or from deficient absorption or activation of vitamin D.¹²⁴ The term *rickets* applies to the defective mineralization of bone and the cartilaginous growth plate in growing children. As shown in Table 101-8, osteomalacia or rickets may result from decreased availability of vitamin D as a consequence of insufficient ultraviolet light exposure, insufficient

Table 101-8 Causes of Osteomalacia and Rickets

Vitamin D Deficiency or Dysfunction
Reduced Availability
Nutritional deficit
Reduced exposure to ultraviolet light
Malabsorption (gastrointestinal or biliary disease, surgical resection)
Alteration in Metabolism
Reduced 25-hydroxyvitamin D from liver or gastrointestinal disease, nephrotic syndrome, anticonvulsant drugs
Reduced 1,25-dihydroxyvitamin D from renal disease, vitamin D-dependent rickets type I
Alteration in Action on Target Tissues
Vitamin D-dependent rickets type II
Phosphate Deficiency
Decreased availability—dietary deficiency, phosphate-binding antacids
Decreased renotubular phosphate reabsorption
Familial—X-linked hypophosphatemic rickets, adult-onset vitamin D-resistant osteomalacia
Acquired—hypophosphatemic osteomalacia (phosphate diabetes), oncogenic osteomalacia
Generalized renotubular disorders
Acidosis
Renotubular acidosis
Ureterosigmoidostomy
Carbonic anhydrase inhibitors (acetazolamide)
Miscellaneous Mineralization Defects
Inhibitors of mineralization—fluoride, bisphosphonates (e.g., etidronate), chronic renal failure (aluminum)
Hypophosphatasia

Modified from LeBoff MS, Brown EM: Metabolic bone disease. In Hare JW, editor: *Signs and symptoms in endocrine and metabolic disorders*, Philadelphia, 1986, JB Lippincott, pp 239–260.

vitamin intake, or malabsorption in patients with gastrointestinal or biliary disorders. Reduced levels of 25-OHD are caused by severe liver disease, increased renal excretion of vitamin D metabolites due to nephrotic syndrome, or accelerated metabolism of 25-OHD caused by anticonvulsant drugs. Decreased activation of 1,25(OH)₂D is seen in patients with renal insufficiency due to increased phosphate levels; the resultant lower ionized calcium levels lead to secondary or tertiary hyperparathyroidism.

A careful history is important in the diagnosis of osteomalacia or vitamin D insufficiency. For example, a history of a malabsorptive process such as gastrectomy, intestinal resection, sprue, primary biliary cirrhosis, or pancreatic deficiency may lead to the identification of vitamin D deficiency and osteomalacia.¹²⁴ Patients with osteomalacia may present with generalized pain involving the pelvis, spine, ribs, or lower extremities or with skeletal deformities such as bowing of the long bones, kyphoscoliosis, or pelvic abnormalities. Another clinical sign of osteomalacia in adults is proximal muscle weakness, which may result in an antalgic or waddling gait and difficulty ambulating.

Pain may be elicited by deep palpation of the tibia, ribs, or pubic ramus.¹²⁴ One of the radiographic signs of osteomalacia is the presence of pseudofractures, or Looser's zones, which are transverse lines of rarefaction through the cortices, with incomplete healing in the ribs, scapulae, long bones (Figure 101-2), or pubic rami. Pseudofractures,

Figure 101-2 Osteomalacia and fractures in a 65-year-old woman with malabsorption. Shown are a pseudofracture of the left lesser trochanter and an avulsion of the right lesser trochanter. This patient also had previous bilateral pubic rami fractures.

however, may be indistinguishable from those associated with osteogenesis imperfecta or Paget's disease. Other radiographic findings in osteomalacia are vertebral fractures or protrusio acetabuli. Vitamin D deficiency may result in irreversible cortical bone loss.¹²⁴ In subtle cases of osteomalacia, a bone biopsy with a double tetracycline label may be necessary; characteristic histomorphometric findings in this disorder include increased osteoid and delayed mineralization of bone.

Rickets causes abnormalities of the epiphyseal growth plate, and the clinical signs include an inability to ambulate, growth disturbances, bowing of the long bones, and short stature. Bony deformities of the skull and ribs may develop, with widened cranial sutures (craniotabes), thickened costochondral junctions (rachitic rosary), or indentation of the margins of the ribs (Harrison's grooves).

The biochemical parameters in patients with osteomalacia reflect the underlying pathophysiologic process and the compensatory biologic responses. In vitamin D deficiency states, the serum calcium levels are usually normal or slightly decreased because PTH levels rise rapidly as a compensatory response to impaired calcium absorption.¹²⁵ In renal insufficiency phosphate retention, impaired renal production of $1,25(\text{OH})_2\text{D}$, hypocalcemia, and skeletal resistance to PTH are thought to lead to the development of hyperparathyroidism and resultant renal osteodystrophy, mixed osteomalacia, and osteitis fibrosa cystica.¹²⁶ Also, aluminum intoxication may present with pure osteomalacia or adynamic bone disease.^{125,127} Chronic vitamin D deficiency may increase the secretory demands of the parathyroid glands, thereby producing secondary or, in some instances, tertiary hyperparathyroidism. In patients with osteomalacia without hepatobiliary disease, alkaline phosphatase levels are often elevated.¹²⁴

Osteomalacia may be associated with a deficiency of phosphate, principally in patients with decreased renotubular reabsorption of phosphate. Familial hypophosphatemic vitamin D-resistant rickets in children or osteomalacia in adults usually presents with renal phosphate leak, hypophosphatemia, rachitic or osteomalacial changes, and inappropriately normal or low-normal $1,25(\text{OH})_2\text{D}$ level for the degree of hypophosphatemia. This X-linked dominant

disorder may present in young children with the inability to walk, followed by progressive bowing and skeletal deformities, without signs of proximal myopathy. The genetic locus for X-linked hypophosphatemic rickets has been mapped to Xp22.1, and the gene is named *PHEX* (phosphate-regulating gene with homology to endopeptidases on the X chromosome).¹²⁸

Oncogenic osteomalacia or rickets is a vitamin D-resistant process associated with certain neoplasias, principally small, benign mesenchymal or endodermal tumors and, infrequently, certain malignant tumors (e.g., multiple myeloma; prostatic, oat cell, breast carcinomas).^{129,130} Such patients typically present with decreased renotubular phosphate reabsorption, hypophosphatemia, muscle weakness, diminished $1,25(\text{OH})_2\text{D}$ levels, and normocalcemia. The benign tumors tend to be small and difficult to identify on physical examination or radiographs. Surgical removal of these tumors results in a rise in the phosphate and $1,25(\text{OH})_2\text{D}$ levels and resolution of the skeletal process. Osteomalacia may also be associated with generalized renotubular disorders and the use of certain drugs that contain inhibitors of mineralization (e.g., fluoride, etidronate, aluminum). The evaluation of a patient suspected of having osteomalacia is outlined in Table 101-9.

Osteomalacia is often a treatable disease, but the diagnosis may be overlooked. Vitamin D deficiency can be treated with physiologic doses of vitamin D, but higher doses (1000 to 2000 IU/day) may hasten the healing of bone. In the presence of intestinal malabsorption, and until the underlying malabsorptive process is corrected, large doses of vitamin D (50,000 IU once a week to three or more times a week) are often required. Careful monitoring of the serum and urinary calcium levels and 25-OHD concentrations is necessary to prevent vitamin D intoxication. Use of the active metabolite of 25-OHD (Calderol) may occasionally be necessary in resistant patients or in those with severe liver disease who cannot achieve activation of this metabolite. The potential advantages of using 25-OHD are more stable bioavailability, shorter half-life, and greater potency than the parent compound,¹²⁴ although the cost is greater.

In patients with hypophosphatemia and disorders of renotubular phosphate reabsorption, mineralization of bone occurs with phosphate therapy and moderately high doses of $1,25(\text{OH})_2\text{D}$, the latter being necessary to prevent the secondary hyperparathyroidism associated with phosphate therapy. In patients with renal insufficiency or failure, a phosphate binder (calcium acetate or calcium carbonate) should be used after meals to decrease intestinal phosphate absorption. Calcium citrate therapy should not be used because it augments aluminum absorption. In those with

Table 101-9 Evaluation of Osteomalacia

Calcium, phosphorus, alkaline phosphatase, urinary calcium levels; 25-hydroxyvitamin D and intact parathyroid hormone levels
In selected patients:
1,25-Dihydroxyvitamin D levels (e.g., renal insufficiency, vitamin D-resistant osteomalacia or rickets)
Vitamin D absorption test: obtain 25-hydroxyvitamin D levels at 0, 4, and 8 hr (e.g., some cases of malabsorption)
Tubular reabsorption of phosphate (e.g., vitamin D-resistant osteomalacia or rickets)
Bone biopsy with double tetracycline labels

renal failure, 1,25(OH)₂D therapy administered orally^{125,131} (or intravenously in some dialysis patients) suppresses parathyroid cell secretion and proliferation; a threefold elevation of the PTH level is advocated by some investigators to prevent adynamic bone disease.¹²⁶ Analogues of 1,25(OH)₂D that do not produce hypercalcemia but decrease levels of PTH are now available and may be useful in patients with renal insufficiency.

PAGET'S DISEASE OF BONE

Paget's disease of bone affects approximately 2% to 3% of the population older than 50 years and is uncommon in individuals younger than 40 years.¹³² Paget's disease is characterized by enhanced resorption of bone by giant, multinucleated osteoclasts, followed by the formation of disorganized woven bone by osteoblasts. The resultant bone is expanded, weak, and vascular, so affected bones may become enlarged and deformed and the overlying skin may feel warm to the touch.¹³³

Cause

The cause of Paget's disease is uncertain, although data showing the presence of viral inclusion particles in giant pagetic osteoclasts support a viral cause, possibly associated with measles, respiratory syncytial, or canine distemper virus. Paget's disease tends to aggregate in families in an autosomal dominant pattern, and 40% of patients have at least one other family member affected.¹⁰⁷ Recently, in a family with juvenile Paget's disease, the disease was found to be associated with a polymorphism in the OPG allele.¹³⁴ Studies of additional families with this mutation may lead to the discovery of the cause of Paget's disease.

Clinical Features

Many patients with Paget's disease are asymptomatic, and the disease is detected by the incidental finding of an elevated alkaline phosphatase level or characteristic radiographic abnormality. Other patients present with a range of symptoms that include bone pain; skeletal deformities (bowing of long bones, enlarged skull, pelvic alterations); pathologic fractures; increased cardiac output (with extensive disease); and nerve compression. Paget's disease typically includes a lytic phase, a combined lytic and blastic phase, and a sclerotic or "burned out" phase occurring late in the disease process.

Radiographic signs of the three stages of Paget's disease may be present at different sites in the same patient.¹³² The skeletal sites commonly involved with Paget's disease include the skull (Figure 101-3), vertebrae, pelvis, sacrum, and lower extremities. Degenerative joint disease may develop adjacent to the bones and cause pain that may obscure the symptoms associated with Paget's disease.¹³² Ten percent to 30% of patients with Paget's disease may experience fractures that present initially as asymptomatic or painful short fissure fractures traversing the bony cortex (Figure 101-4). Complete fractures of the bones such as the "chalk stick" fracture also occur; fractures of the long bones may be a serious complication because the increased vascularity of pagetic bone may lead to excessive blood loss.

Figure 101-3 Paget's disease of the skull in a woman with signs of increasing head size and progressive hearing loss. The alkaline phosphatase level was 2100 U/L. This computed axial tomogram shows marked thickening of the inner and outer skull tables, with osteoblastic pagetoid changes. Audiologic evaluation revealed bilateral hearing loss.

Healing of fractures in pagetic bone usually occurs normally, although there have been reports of nonunion. A rare complication of Paget's disease of bone is sarcomatous degeneration in less than 1% of patients (with osteogenic sarcomas or, less commonly, fibrosarcomas or chondrosarcomas); these patients generally have a poor prognosis. The development of a sarcoma may be heralded by the presence of a soft tissue mass, localized pain, and rise in the alkaline phosphatase level.

Figure 101-4 Paget's disease of the proximal femur. Note the coarse trabeculae, thickened cortices, lateral fissure fracture, and expanding lytic region characteristic of the "blade-of-grass" lesion.

Neurologic symptoms generally result from compression of the nerves by pagetic bone. Hearing loss is common and is caused by sensory loss and conduction abnormalities due to pagetic involvement of the bones of the inner ear. Paget's disease of the skull may also produce ocular and other cranial nerve palsies. Compression of the base of the skull may lead to basilar invagination, cerebellar dysfunction, or obstructive hydrocephalus, with symptoms of nausea, ataxia, incontinence, gait disturbances, and dementia. Neurologic compromise of the thoracic or lumbar spine may lead to spinal cord compression or, in the latter instance, cauda equina syndrome.

Laboratory Findings

Biochemical indices in patients with Paget's disease usually show normal serum calcium and phosphate levels, although hypercalcemia may develop with immobilization when there is an uncoupling of bone resorption and formation. Patients with Paget's disease may also be hypercalcemic if they coincidentally acquire primary hyperparathyroidism, which can further increase bone remodeling and worsen the disease process. Secondary hyperparathyroidism may develop in approximately 10% to 15% of patients with Paget's disease, presumably because of inadequate calcium intake to meet the skeletal demands of the heightened bone remodeling.¹³²

Alkaline phosphatase levels of bone origin (BSAP) are commonly elevated in patients with significant Paget's disease because of the increased osteoblastic activity combined with bone breakdown. In the absence of liver disease, the alkaline phosphatase level typically correlates with the extent of the pagetic involvement of bone, although it may be more elevated in Paget's disease of the skull (see Figure 101-3).

Unexpectedly, circulating osteocalcin levels do not reflect disease activity in patients with Paget's disease as well as bone-specific alkaline phosphatase levels reflect disease activity. Markers of bone resorption such as urinary collagen cross-links like N telopeptides and C telopeptides are also elevated in active Paget's disease. Other laboratory abnormalities in patients with Paget's disease include hypercalciuria, hyperuricemia, and hyperuricemia, possibly related to the increased turnover of osteoclasts. Serum uric acid levels should be measured periodically because of the association of Paget's disease with gouty arthritis.

Diagnosis

Bone scans are valuable tools for assessing the extent of Paget's disease and are therefore useful as part of the initial evaluation.¹³³ As diagnostic tests, however, bone scans in general are sensitive but not specific for a number of skeletal processes. Radiographs show characteristic radiologic findings such as transverse lucent areas, osteoporosis circumscripta, enlargement of the bones, expanding lytic changes, the "blade-of-grass" lesion shown in Figure 101-4, thickened cortices, a coarse trabecular pattern, or sclerotic changes.

In patients with involvement of the skull and changes in mental status, a skull radiograph, magnetic resonance imaging (MRI), or quantitative computed tomography

(QCT) may be useful to diagnose platybasia and flattening of the base of the skull, basilar invagination, or the infrequent complication of hydrocephalus. Audiologic evaluation may reveal hearing loss in patients with pagetic involvement of the skull.

Treatment

The indications for treatment of Paget's disease (Table 101-10) include pain, hypercalcemia, fractures, high-output cardiac failure (rare), and neurologic compromise. Therapy can also be used to prevent the progression of deformity or risk of nerve compression when there is pagetic involvement of the skull, a vertebral body, or a weight-bearing bone (femur) or when disease is present adjacent to a major articular joint.

Treatment of symptomatic Paget's disease is usually directed at suppression of the enhanced bone resorption and skeletal turnover with calcitonin or bisphosphonates.^{132,135} Response to therapy is monitored by the reduction of symptoms and maintenance of the alkaline phosphatase level in a mid-normal range, with retreatment once values rise 25% above normal.

Calcitonin

Salmon calcitonin and human calcitonin inhibit the function of osteoclasts, which are active in the pagetic process; both types of calcitonin preparations come in an injectable form and are FDA approved for patients with Paget's disease.¹³⁶ Salmon calcitonin therapy is usually initiated at a low dose to ensure patient tolerance and then increased to a daily dose of 100 Medical Research Council units (intramuscularly or subcutaneously). After 6 months of therapy, the patient may be maintained on 50 to 100 Medical Research Council units daily.¹³² Approximately two-thirds of patients show a decrease in alkaline phosphatase levels of 50% or more in 2 to 6 months. Some patients experience resistance to the effects of calcitonin, which can be reversed in some instances by switching from salmon calcitonin to human calcitonin. Calcitonin is a safe drug.

Calcitonin is useful in patients with expanding lytic lesions, particularly of a weight-bearing bone, or for preoperative therapy before elective orthopedic procedures. The use of calcitonin nasal spray has few systemic side effects but is not FDA approved for the treatment of Paget's disease.

Bisphosphonates

Several bisphosphonates are currently approved by the FDA for the treatment of Paget's disease; they include

Table 101-10 Indications for Treatment of Paget's Disease of Bone

Pain
Hypercalcemia
Fractures
High-output cardiac failure (rare)
Skull involvement
Neurologic compromise
Periarticular disease
Prevention of progression of Paget's disease

etidronate disodium (Didronel), pamidronate (Aredia), alendronate (Fosamax), tiludronate disodium, risedronate (Actonel), and zoledronic acid (Reclast).

Etidronate disodium is an orally administered drug that produces a clinical and biochemical response similar to that of calcitonin.¹³⁶ The therapeutic dose for Paget's disease is 5 mg/kg per day (400 mg/day, or a minimum of 200 mg/day for smaller patients) for 6 months; the drug is then stopped for 6 months before being reinstituted in 6-month cycles of therapy.¹³⁷ As mentioned previously, higher doses of etidronate are associated with defective mineralization of bone and osteomalacia, with symptoms of pain and fractures. Measurements of alkaline phosphatase levels at 3- to 6-month intervals are useful to ensure the suppression of bone turnover; an estimated 25% of patients may become resistant to etidronate.¹³² However, newer, more potent bisphosphonates are effective for the treatment of Paget's disease.

Parenteral pamidronate is also approved for the treatment of symptomatic Paget's disease of bone in patients with a threefold or greater elevation of alkaline phosphatase concentrations. This more potent bisphosphonate is useful in patients who become resistant to etidronate and in those with more severe disease. An advantage of this therapy is that alkaline phosphatase levels may be reduced to the normal range, with a sustained response for a prolonged period (up to a year or more).^{132,138}

The FDA-recommended dose of pamidronate for patients with Paget's disease is 30 mg/day as a 4-hour infusion on 3 sequential days (total dose 90 mg), with retreatment possible if necessary. Other regimens for the treatment of Paget's disease include 60 mg of pamidronate daily (infused over 3 hours) once a week for 1 or 2 weeks in patients with alkaline phosphatase levels between 300 and 400 U/L. For more extensive disease, three or four infusions of pamidronate every 1 to 2 weeks may be necessary. To assess the efficacy of these regimens for Paget's disease, clinical symptoms should be reviewed and alkaline phosphatase levels measured 2 to 3 months later.¹³⁸

Some patients treated with pamidronate may experience a transient fever, musculoskeletal and flulike symptoms, and hypocalcemia; calcium supplementation (500 mg twice daily in vitamin D–replete patients) can offset the hypocalcemia that results from the suppression of bone resorption. Pamidronate is available only as a parenteral drug, which restricts its use.¹³⁸

Oral alendronate has been approved for the treatment of Paget's disease at a dose of 40 mg/day for 6 months. Therapy with alendronate is recommended for patients with at least a twofold elevation in alkaline phosphatase levels or for those with specific indications for therapy (see Table 101-10). The use of alendronate produces a normalization of, or a 60% or greater reduction in, the alkaline phosphatase level in approximately 85% of patients. Studies indicate that this therapy is more effective than etidronate. (All bisphosphonates must be taken correctly to minimize gastrointestinal side effects).¹³⁹

Risedronate is another potent bisphosphonate (see Table 101-6) that is FDA approved for the treatment of Paget's disease. Siris and colleagues¹³⁹ treated 162 patients with moderate to severe Paget's disease with oral risedronate (30 mg/day for 84 days, followed by 112 days without

treatment). This cycle was repeated if the serum alkaline phosphatase level did not normalize or increased more than 25% from its nadir value. After the first and second cycles, the serum alkaline phosphatase level decreased 65% and 69%, respectively, and urine markers decreased 50% and 66.9%, respectively. The serum alkaline phosphatase level normalized in 53.8% of patients, and a significant decrease in bone pain was noted. Risedronate is well tolerated and has few adverse effects including a flulike syndrome, gastrointestinal symptoms, and, rarely, iritis. Other groups have shown a decrease in serum alkaline phosphatase levels of 79% and 86%, with an 85% and 100% decrease in urine markers.¹⁴⁰ There is no evidence of osteomalacia in bone biopsies from patients treated with 30 mg of risedronate. Patients who have become resistant to etidronate appear to respond to risedronate. Patients must be instructed to have an adequate intake of calcium and vitamin D while taking risedronate. Recently, zoledronic acid was also found to be effective in the treatment of Paget's disease, and approval is pending from the FDA.¹⁴¹

In addition to antiresorptive therapies, nonsteroidal anti-inflammatory drugs (NSAIDs) and aspirin are useful modalities to alleviate the joint pain and other symptoms that result from degenerative joint disease. Finally, surgical intervention is sometimes warranted in patients with Paget's disease and bony deformities, pathologic fractures, nerve compression, or degenerative arthritis. Orthopedic procedures such as total joint replacement and osteotomies are associated with a reduced risk of intraoperative bleeding or other complications if patients are treated medically (e.g., with calcitonin or other bisphosphonates) to reduce the disease activity and vascularity for at least 6 weeks before the procedure.

OTHER MEDICATION-INDUCED OSTEOPOROSIS

Aromatase inhibitors in women undergoing breast cancer treatment are associated with bone loss. Postmenopausal women maintain a low level of circulating estrogen because of aromatization of androgens to estrogen in tissues such as fat and muscle by cytochrome P-450 enzyme. Inhibition of this enzyme is now used in postmenopausal women with breast cancer. There are two classes of aromatase inhibitors: nonsteroidal reversible inhibitors (anastrozole and letrozole) and steroidal reversible inhibitors (exemestane). Because these agents prevent the conversion of androgen to estrogen, this results in low serum estrogen levels and increased bone remodeling. Fracture rates in clinical trials of aromatase inhibitors compared with either tamoxifen or placebo ranged from 3% to 7%.¹⁴² In a 2-year study, significantly higher markers of bone turnover and nearly twice the lumbar spine bone loss and fracture rates were observed with anastrozole compared with tamoxifen.¹⁴² Although the data are just beginning to be collected regarding skeletal health in women treated for breast cancer with aromatase inhibitors, it is important to obtain a history of clinical risk factors for osteoporosis and a BMD measurement of the hip and spine. Preventive treatment should be initiated in women with normal or low bone mass and no history of fractures. Treatment of women with low bone mass (t score ≤ -2)

should be initiated with potent antiresorptive agents, and BMD should be monitored at least every 2 years. Recent studies with zoledronic acid and denosumab have been reported to be quite effective in this patient population.^{143,144} If a woman continues to lose bone mass on aromatase inhibitors despite compliance with potent antiresorptive agents, and if the patient has not had radiation to the skeleton as part of the breast cancer protocol, rPTH 1-34 treatment can be used to build up bone mass.

Gonadotropin-releasing hormone antagonists are used to treat women with endometriosis and men with prostate cancer. These compounds induce bone loss by lowering estrogen levels, resulting in accelerated bone turnover. A study of more than 50,000 men with prostate cancer treated with androgen-deprivation therapy consisting of either gonadotropin-releasing hormone agonists or orchiectomy found an increased risk of fracture or hospitalization due to fracture. Although the overall risk of fracture associated with androgen-deprivation therapy was only modestly increased overall, the risk of fracture was significantly associated with the number of doses of gonadotropin-releasing hormone agonists. Other studies have reported that androgen-deprivation therapy increases bone loss at all sites, with a 2% to 8% annual loss in the lumbar spine and a 2% to 6% loss in the hip after 1 year.¹⁴⁵ Given the high incidence of prostate cancer and the increasing use of this treatment, assessment of bone mass and the prevention of additional bone mass loss are probably appropriate. Oncologists currently recommend that BMD be measured at the time of initiation of androgen-deprivation therapy and that clinical risk factors for osteoporosis be reviewed including history of fracture after age 30, family history of hip fracture, smoking history, use of glucocorticoids, low testosterone level, and rheumatoid arthritis. If the patient has a low BMD (t score < -2.5) or a t score between -1 and -2.5 and other risk factors, treatment with calcium and vitamin D supplementation and a bisphosphonate (zoledronic acid, alendronate, risedronate, or denosumab) should be initiated. BMD of the lumbar spine and hip should be measured at least once a year while patients are maintained on androgen-deprivation therapy.¹⁴⁶⁻¹⁴⁹

Proliferative Bone Diseases

REUVEN MADER

KEY POINTS

Diffuse idiopathic skeletal hyperostosis (DISH) is usually defined by the presence of large flowing osteophytes connecting at least four vertebrae, typically in the thoracic spine. However, the disease often involves the cervical and lumbar spine and peripheral joints, especially entheses.

The etiology of DISH is unclear, but it is associated with a variety of metabolic abnormalities, many of which are also seen in type II diabetes.

Treatment of spinal DISH is mostly symptomatic, but patients and physicians need to be aware of the increased fracture risk of these patients.

Patients with DISH are at increased risk for heterotopic bone formation after joint surgery, and appropriate prophylactic measures should be carried out.

Because of the metabolic abnormalities associated with DISH, many of which are also cardiac risk factors, the discovery of the disease such as an incidental finding on chest x-ray should prompt careful evaluation of known cardiovascular risk factors.

Hypertrophic osteoarthropathy can be seen in many conditions, but growth factors such as platelet-derived growth factor and vascular endothelial growth factor are implicated as the common etiology of most, if not all, cases.

Hypertrophic osteoarthropathy usually responds dramatically to effective treatment of the primary disease such as surgical resection of a lung carcinoma.

SAPHO (synovitis, acne, pustulosis, hyperostosis, and osteitis) syndrome is a chronic inflammatory disorder, often relapsing, of unknown etiology. The most common sites of bone involvement are in the anterior chest wall, mainly the clavicles, sternum, and sternoclavicular joint.

Although the etiology of SAPHO syndrome is unknown, infectious etiology has been proposed on the basis of isolation of *Propionibacterium acnes* from sternal osteosclerotic lesions.

Nonsteroidal anti-inflammatory drugs (NSAIDs) are usually the first line of treatment in SAPHO and may improve the symptoms. However, additional therapy with other modalities is often required. Several empiric therapeutic approaches have been reported in SAPHO including NSAIDs, corticosteroids, bisphosphonates, sulfasalazine, methotrexate, antibiotics, and anti-tumor necrosis factor agents.

Proliferative bone diseases encompass a variety of conditions characterized by exuberant bone and enthesal ossifications and calcifications. New bone formation is the main feature in diffuse idiopathic skeletal hyperostosis (DISH) and hypertrophic osteoarthropathy (HOA) and is a common finding in osteoarthritis. New bone formation may also accompany some spondyloarthropathies such as ankylosing spondylitis, psoriatic arthritis, and sternoclavicular syndrome, also known as SAPHO (synovitis, acne, pustulosis, hyperostosis, and osteomyelitis). New bone formation has also been described in endocrine diseases, however, such as thyroid disorders, acromegaly, and hypoparathyroidism (Table 102-1).¹⁻³ Osteoarthritis, spondyloarthropathies, and endocrine disorders are discussed elsewhere in this book.

DIFFUSE IDIOPATHIC SKELETAL HYPEROSTOSIS

DISH is a condition characterized by calcification and ossification of soft tissues, mainly ligaments and entheses. This condition was described by Forestier and Rotes-Querol in 1950⁴ and was termed *senile ankylosing hyperostosis*. There is a marked predilection to the axial skeleton, particularly the thoracic spine. Recognition that the condition is not limited to the spine and may involve peripheral joints led researchers to coin the name *DISH*, a term now widely used.⁵

DISH is characterized by the production of coarse, flowing osteophytes involving, in particular, the right side of the thoracic spine with preservation of the intervertebral disk space and by ossification of the anterior longitudinal ligament. Calcification and ossification of the posterior longitudinal ligament seem to be additional skeletal manifestations of DISH. Other enthesal regions might be affected such as the peripatellar ligaments, Achilles tendon insertion, plantar fascia, olecranon, and others.⁶⁻⁸

The diagnosis is usually based on the definition suggested by Resnick and Niwayama.⁵ This radiographic approach requires the presence of flowing, coarse osteophytes on the right side of the thoracic spine, connecting at least four contiguous vertebrae, or ossification of the anterior longitudinal ligament, preserved intervertebral disk height in the involved segment, and the absence of apophyseal joint ankylosis and sacroiliac joint involvement (Table 102-2).⁸ Another set of criteria, for epidemiologic purposes, was suggested by Utsinger.⁷ These criteria consider also peripheral enthesopathies. A definite diagnosis of DISH is established by criteria similar to those suggested by Resnick and Niwayama. A probable diagnosis of DISH is possible, however, with continuous ossification or calcification, or both, of the anterolateral aspect of at least two contiguous

vertebral bodies and bilateral well-corticated enthesopathies in the heel, olecranon, and patella. It has also been suggested that peripheral enthesopathies might represent early DISH, which may evolve, over time, to its full radiographic appearance.

Epidemiology

DISH is more common in men than women. An autopsy study reported that in a series of 75 spines studied at autopsy, 28% had DISH.⁹ The reported prevalence of DISH varies according to age, ethnic origin, geographic location, and clinical setting (i.e., hospital based versus population based). In a study of a North American metropolitan hospital population, the prevalence in men and women older than 50 years of age was reported to be 25% and 15%, respectively, and the prevalence in men and women older than 70 years was 35% and 26%, respectively.¹⁰ Similar figures were reported for patients from Budapest.¹¹ Higher figures were reported for Jews older than 40 years living in Jerusalem, reaching a prevalence of 46% for men older than 80.¹² A much smaller prevalence was reported from Korea, barely reaching 9% in the older age group.¹³ Native Africans had a prevalence of 13.6% in patients older than 70 years of age with no difference between men and women.¹⁴ In population-based, as opposed to hospital-based, studies, the reported prevalence was slightly greater than 10% in patients older than 70 years of age.¹⁵ Mild DISH was found in human remains dating back 4000 years. In human remains from the 6th to 8th centuries, the prevalence of DISH was higher in men than in women, reaching 3.7%. Although these studies were performed on different and relatively young populations, it seems that the prevalence of DISH is increasing.^{16,17}

Etiology and Pathogenesis

The etiology of DISH is unknown. Several metabolic, genetic, and constitutional factors were reported to be associated with this condition, however, including obesity,

Table 102-3 Conditions Associated with Diffuse Idiopathic Skeletal Hyperostosis

a high waist circumference ratio, hypertension, diabetes mellitus, hyperinsulinemia, dyslipidemia, elevated growth hormone levels, elevated insulin-like growth factor (IGF)-I, hyperuricemia, use of retinoids, and genetic factors (Table 102-3).¹⁸⁻²⁶

The association of DISH with excess body weight has been well known since the early descriptions by Forestier and others.^{9,27} This association was reiterated in a study in which patients with DISH were compared with healthy individuals and patients with spondylosis.²⁸ The association of DISH with diabetes mellitus was reported in several studies.^{23,26} It was reported more recently that the prevalence of DISH is no higher in diabetic patients than in nondiabetic subjects, suggesting re-evaluation of diabetes as a risk factor for the development of DISH.²⁹ More often, DISH was reported to be associated with more complex metabolic and endocrine derangements, with or without overt type II diabetes mellitus, comprising glucose intolerance, hyperinsulinemia, dyslipidemia, hyperuricemia, and elevated levels of growth hormone and IGF-I.^{19-20,22} Due to these metabolic abnormalities, patients with DISH have a higher likelihood to be affected by metabolic syndrome and are subjected to a higher coronary artery disease risk.³⁰

Hyperinsulinemia has a profound effect on ligaments and entheses, which is independent of age and obesity. The differentiation of mesenchymal cells in ligaments into chondrocytes and the subsequent endochondral ossification is promoted by insulin.²⁴ The enthesis provides the growth plate for tendons and ligaments in children and persists into adulthood. This particular structure is composed of collagen fibers, fibroblasts, chondrocytes, and calcified matrix, which is probably a target for the ossification process promoted by insulin.¹⁸ Bone morphogenetic protein-2 is a potent osteogenic factor that promotes differentiation of mesenchymal stem cells into osteoblasts and chondroblasts. It stimulates cell proliferation, alkaline phosphatase (ALP) activity, and collagen synthesis.³¹ Its ability to promote mineralization is inhibited by matrix Gla protein, which is highly expressed in bone and cartilage. Matrix Gla protein deficiency or its altered carboxylation may cause a high level of bone morphogenetic protein-2 activity that leads to hyperostosis.²⁶

The enthesis may also be under the influence of other growth-promoting peptides. Elevated growth hormone levels were reported in DISH. Growth hormone is capable of inducing osteoblast cell proliferation and may promote local production of IGF-I, which mediates the action of growth hormone and can stimulate ALP activity in

Table 102-2 Suggested Diagnostic Criteria for Diffuse Idiopathic Skeletal Hyperostosis

Flowing calcification and ossification along the anterolateral aspect of at least four contiguous vertebral bodies

Absence of apophyseal joint bony ankylosis and sacroiliac joint erosion, sclerosis, or intra-articular osseous fusion

osteoblasts.^{19,26,32,33} ALP promotes the calcification process during bone formation and is considered a good indicator for the maturation stages of osteoblasts.^{34,35} There is no explanation yet as to why the new bone formation is localized mainly at the ligamentous and enthesal sites. In male DISH patients, growth hormone serum levels were not elevated in the serum but were much higher in the synovial fluid.³⁶ In the spine, vertebral blood supply could be a factor in the onset or progression of DISH.³⁷ Intraerythrocyte growth hormone levels may exceed serum growth hormone levels and could be transported to the vertebral site by the mechanism described by Denko and colleagues.³⁶

The expression of various genes involved in cell division and growth is regulated by nuclear factor κ B (NF κ B), which is capable of regulating the differentiation of multipotential cells. It was shown that activation of environmental factors such as platelet-derived growth factor (PDGF)-BB and transforming growth factor (TGF)- β 1 in ligament cells stimulates the activation of NF κ B, which influences the osteoblastic differentiation of mesenchymal cells. This event is accompanied by elevation of ALP activity in cells of patients with DISH and serves as an indicator of maturation stages of the osteoblast.³⁴ Inflammatory cytokines such as PDGF-BB, TGF- β 1, and others may be related to the onset of non-insulin-dependent diabetes mellitus and may be the link between this condition and the occurrence of DISH.^{38,39}

Vitamin A and its derivatives have been implicated in the pathogenesis of DISH owing to their ability to promote new bone formation. Levels of vitamin A were reported to be higher in patients with DISH compared with controls, and some reports showed DISH-like manifestations in young patients treated with vitamin A or its derivatives.^{20,40} The role of vitamin A is unclear, however, because more recent studies did not show an increased prevalence of DISH among patients treated with vitamin A in various dosages and for various lengths of time.^{22,25,28} Larger prospective studies are necessary to elucidate the role played by this vitamin in the pathogenesis of DISH.

Familial clustering of DISH or families with early presentation of DISH suggest a genetic background for this disorder.^{41,42} Ossification of the posterior longitudinal ligament is closely related to DISH, and the two conditions can coexist. *COL6A1*, which is the candidate gene for ossification of the posterior longitudinal ligament, was reported to be significantly associated with DISH in Japanese, but not in Czech, patients.^{43,44} This finding would suggest that other factors might play an important role in the genetic predisposition for the development of DISH.

There are no convincing explanations for the predilection of the hyperostotic process to affect the anterolateral aspect of the thoracic spine. The limited range of motion of the thoracic spine has been cited as a possible cause for the predilection to this site. This assumption cannot explain the involvement of the extremely mobile cervical spine or the lumbar spine, however. The less frequent involvement of the left side of the thoracic spine was ascribed to the pulsation of the aorta. This assumption was based on a few reports that described left-sided bridging osteophytes in cases with a right-sided aorta, suggesting that the aortic pulsations interfere with the production of the osteophytes.⁴⁵ Calcifications, ossification, and subsequent stiffening of

ligaments and joint capsules have important pathogenetic implications.

Osteoarthritis may have pathogenetic features in common with the peripheral joint manifestations of DISH. It was suggested that in the small non-weight-bearing joints in osteoarthritis, the process is caused by an increased intra-articular pressure and subsequent development of “crash” forces.⁴⁶ This development was attributed to thickening of the collateral ligaments of these joints that enforce a constraint movement, not to primary damage to the cartilage. It seems reasonable that the joints affected by DISH may develop the same “crash” forces operating in small osteoarthritis joints, as a result of this mechanism. This mechanism might explain the involvement of “atypical” joints, not commonly affected by osteoarthritis, and the hypertrophic osteoarthritic changes in the commonly affected joints.

Clinical Manifestations

The lack of specific symptoms and signs of DISH, as well as the radiographic diagnostic criteria, have raised doubts about DISH as a separate entity.⁴⁷ Although the disease may be asymptomatic, it was reported to be associated with morning stiffness, dorsolumbar pain, and reduced range of motion in most patients.^{7,8} Patients with DISH may have extremity pain involving peripheral large and small joints and peripheral entheses such as the heel, Achilles tendon, shoulder, patella, and olecranon. Pain in the axial skeleton may involve all three segments of the spine and the costosternal and sternoclavicular joints. The level of pain and disability is significantly higher compared with healthy subjects but is not different from patients with spondylosis.²⁸ Complaints of pain referable to the thoracic spine are common and are accompanied by a reduced chest expansion.

Although similar in some aspects to osteoarthritis of the spine, DISH is a distinct clinical entity with different characteristics.⁴⁸ Classically, the portions of the spine that are involved in osteoarthritis are the lower portions of the cervical spine and the lumbar spine. Thoracic spine involvement is uncommon in osteoarthritis or occurs in late stages of the disease, as opposed to the common involvement of the thoracic spine in DISH. Thoracic spine involvement in DISH is characterized by preserved intervertebral height, whereas in spinal osteoarthritis, reduced intervertebral disk height is common. These differences in the radiologic appearance and anatomic spinal distribution probably have to do with the different pathogenetic mechanisms described earlier. It is presumed that the primary target for the osteoarthritic process is the cartilage represented in the spine by the intervertebral disks and the cartilage of the facet joints.

The wear-and-tear forces operating in the extremely mobile lower cervical and lumbar portions of the spine might explain the frequent involvement of these segments in osteoarthritis, whereas the thoracic spine is the least mobile of the spinal segments. The main targets of the disease in DISH are the spinal ligaments and entheses (Figure 102-1).^{5,49} These abnormalities are not limited to the thoracic spine and may involve the lumbar spine and the cervical spine (Figure 102-2). In the lumbar spine, the large bridging osteophytes are not uniformly one-sided.⁵⁰

Figure 102-1 Large, flowing, right-sided osteophytes of the thoracic spine (A). Note the translucent area between the vertebral body and the ossified ligamentous tissue (B).

These sites of ossification and the subsequent production of large osteophytes may result in spinal stenosis⁵¹ and spinal stiffening, which increases the risk of fractures.⁵² These fractures may be unrecognized, unstable, and associated with treatment delays and permanent neurologic deficits. Severe complications may develop, especially when the cervical

spine is affected including dysphagia, hoarseness, stridor, ossification of the posterior longitudinal ligament, myelopathy, aspiration pneumonia, sleep apnea, atlantoaxial complications, thoracic outlet syndrome, esophageal obstruction, endoscopic and intubation difficulties, and fractures (Table 102-4).⁵³ The high prevalence of coexisting intervertebral disk damage in young patients with DISH suggests an important role for DISH in the pathogenesis of spondylosis in this group of patients.⁵⁴ At times, patients with DISH may assume the typical postural abnormalities of advanced ankylosing spondylitis such as accentuated kyphosis and reduced mobility of the spine. These two entities, although they may coexist, can usually be distinguished by the different age of onset, clinical presentation, radiographic appearance of the spine and sacroiliac joints, and HLA-B27 associations.^{55,56}

Clinical manifestations similar or identical to those of osteoarthritis are prominent features of DISH in the peripheral joints. The peripheral joints affected by DISH have features that distinguish them from primary osteoarthritis, however. One is the more frequent involvement of joints that are not usually affected in osteoarthritis such as the metacarpophalangeal joints, elbows, and shoulders (Figure 102-3).^{57–60} Other features are a more severe hypertrophic disease that may result in a reduced range of motion in the affected joints and calcified and/or ossified prominent enthesopathies.^{59,61,62}

As described previously, the primary event in DISH is thickening, calcification, or ossification of ligaments and entheses. In particular, enthesopathy affecting the peripheral joints has been described.⁶³ The radiographic appearance of peripatellar, cruciate ligament insertion, and pericapsular osseous enthesopathies are some examples of the contribution of DISH to stiffening of the soft tissues surrounding a joint (Figure 102-4).⁶⁴ Enteseal ossification at various sites other than joints such as the heel, ribs, and pelvis is a common finding in DISH. These enthesopathies may become symptomatic exhibiting pain and swelling in the affected region. A high probability for the presence of spinal DISH was noted for ossification of the iliolumbar and sacrotuberous ligaments and with bony overgrowth of the inferior acetabular rim.^{63,65} The tendency for new bone for-

mation puts the patient at risk for the development of heterotopic ossification after joint surgery.

Patients with DISH often have higher body weight and body mass index, waist circumference, and systolic blood pressure.²⁸ These factors and the metabolic abnormalities

Table 102-5 Therapeutic Targets in Diffuse Idiopathic Skeletal Hyperostosis

described earlier put patients at an increased risk for cardiovascular diseases.^{66,67} The diagnosis of DISH should be suspected in patients with osteoarthritis in atypical locations (e.g., elbow), in patients with hypertrophic osteoarthritis, and in patients with large enthesopathies and entrapment neuropathies of uncertain origin. This is particularly true for patients with the associated diseases and metabolic abnormalities discussed earlier. It has been shown that chest radiographs might serve as a screening tool for the diagnosis of DISH with a sensitivity of 77% and specificity of 97%.⁶⁸

Treatment

Treatment of DISH should address several issues. Treatment is expected to alleviate pain and stiffness; prevent, retard, or arrest progression; correct the associated metabolic disorders; and prevent spontaneous or induced complications (Table 102-5).

Specific therapeutic interventions in DISH have not been systematically explored; this is probably related to

Figure 102-4 A and B, Ossified enthesopathies in the peripatellar, olecranon, and humeral epicondyles (arrows).

the inclusion of DISH in the spectrum of osteoarthritis and the assumption that the same therapeutic interventions for osteoarthritis are suitable for DISH. It was suggested more recently that serum levels of growth hormone and IGF-I might be a useful surrogate marker for assessing DISH progression and remission.³¹ It was estimated that a period of at least 10 years is necessary for the pathologic process to evolve completely.⁶⁹ This notion implies that a long observation period is necessary to show that a therapeutic intervention prevents the development of the disease, arrest its progression, or, it is hoped, reverses the pathologic changes.

There are few reports about remedies to alleviate the symptoms of the disease, but some investigators have reported on the beneficial effects of light exercise, heat, analgesics, and nonsteroidal anti-inflammatory drugs (NSAIDs).⁷⁰ Exercise therapy failed to show a significant improvement in the spinal range of motion except for lumbosacral flexion.⁷¹ More recently, the use of locally acting NSAIDs for the treatment of osteoarthritis was shown to be as effective as the same product by oral route, suggesting that locally acting NSAIDs also might be successfully employed for the symptomatic relief of pain and stiffness in the peripheral joints of patients with DISH.⁷² Treatment of symptomatic enthesopathies might be necessary to alleviate local pain and swelling; this can be achieved by local soft applications such as insoles for plantar spurs or protective bandages at other sites. Infiltration of local anesthetic with long-acting corticosteroids might offer at least temporary relief in severely symptomatic cases. When multiple sites are involved, the same therapeutic modalities mentioned for osteoarthritis may be used.

The coexistence of many cardiovascular risk factors places patients with DISH at a higher risk for cardiovascular complications. It seems appropriate to screen these patients for known cardiovascular risk factors and to treat when appropriate. General measures such as weight reduction, adequate physical activity, and a diet low in saturated fat and carbohydrates all might be important in preventing or arresting the progression of DISH. Some of these factors may have pathogenetic implications and may become therapeutic targets. On the basis of present understanding, therapeutic interventions should aim at a reduction of insulin secretion and insulin resistance. In patients with non-insulin-dependent diabetes mellitus, the use of biguanides, which decrease insulin resistance, may offer an advantage over the use of sulfonylureas, which increase insulin secretion. When coexisting hypertension should be treated, medications that might improve insulin resistance such as angiotensin-converting enzyme inhibitors, calcium channel blockers, and α -blockers should be preferred to medications that might worsen insulin resistance such as thiazide diuretics and β -blockers.⁷³ Some growth factors that might have a role in the development of DISH such as NF κ B, PDGF-BB, TGF- β 1, growth hormone, and IGF-I may become targets someday for specific therapeutic interventions.

Some complications can be avoided if taken into consideration. Aspiration pneumonia can be partially avoided if instructions in proper deglutition and preservation of an upright position after meals are carefully explained to the patient. Physicians familiar with DISH can avoid or minimize damage to the cervical spine or to soft tissues in

Table 102-6 Future Considerations in Diffuse Idiopathic Skeletal Hyperostosis

Seek a better understanding of the pathogenetic basis for the disease
Offer a disease-modifying therapeutic approach

patients who might need certain diagnostic or therapeutic interventions such as upper gastrointestinal endoscopy or endotracheal intubation. It is reasonable to adopt the common measures to prevent falls and trauma, especially in elderly patients. Heterotopic ossification after orthopedic surgeries, in particular hip arthroplasty, is common in patients with DISH.⁵⁴ Several therapeutic interventions aimed at abolishing heterotopic ossification such as administration of NSAIDs, anti-vitamin K, and irradiation, have been reported with variable success.^{74,75} Patients in the high-risk group to develop this complication, such as patients with DISH, should be considered candidates for one of these regimens. The therapeutic options are summarized in Figure 102-5.⁷⁶ Many tasks lay ahead to define better, understand the pathogenesis, and delineate effective interventions for this disorder (Table 102-6).

HYPERTROPHIC OSTEOARTHROPATHY

HOA is a well-known entity characterized by skin and bone proliferation. The hallmark and main visual manifestation is a bulbous deformity of the distal end of the digits, also known as *clubbing* or *drumsticks*. Periostosis is a progressive process with predilection for the tubular bones, principally the tibia and fibula. Periostosis is bilateral; is symmetric; and spares the medullary cavity, the axial skeleton, and the skull. The prevalence of the condition is unknown, but it was found in skeletal human remains dating thousands of years ago.⁷⁷ It may be primary or secondary to many other diseases.

Etiology

Primary HOA is an autosomal dominant disorder characterized by periostosis, clubbing, thickening of the skin of the face and scalp, seborrhea, and hyperhidrosis. It is also termed *pachydermoperiostosis*. There is a male predominance with a male-to-female ratio of 9:1 with one peak of presentation in the first year of life and the other in adolescence.⁷⁸

Secondary forms of HOA may manifest as isolated clubbing or with the full spectrum of the disease. Clubbing may be unilateral or bilateral and has been reported to occur in a variety of diseases including pulmonary (most commonly cancers), cardiac, gastrointestinal, neurologic, infectious, vascular, and other diseases (Table 102-7).⁷⁹⁻⁸⁵

Pathogenesis

HOA is characterized by excessive collagen deposition, endothelial hyperplasia, edema, and new bone formation involving mainly the distal extremity and eventually

progressing proximally. Various hypotheses have been generated in an attempt to explain the development of HOA. Most cases with secondary HOA have severe lung or cyanotic heart diseases. It was suggested that megakaryocytes are fragmented into platelets during their passage in the lung capillaries. In severe lung diseases or right-to-left shunts, megakaryocytes or platelet aggregates bypass the pulmonary capillary bed, however, and lodge in the peripheral vasculature of the digits.

It was shown that locally released growth factors such as vascular endothelial growth factor (VEGF) and PDGF were remarkably increased in tissue samples obtained from digits of patients with HOA.⁸⁶ It is feasible that these substances might be responsible for the distal overgrowth of collagen and bone. VEGF was found to be produced by a lung tumor in a patient with HOA. In this case, serum levels of VEGF were high and resection of the tumor reversed the digital clubbing and reduced the serum VEGF levels.⁸⁷ Activation of platelets and endothelial cells was supported by an increase in circulating von Willebrand factor antigen.⁸⁸ Other growth factors have been associated with digital clubbing including hepatocyte growth factor, which was found to be increased in the serum of patients with lung cancer and HOA compared with patients with lung cancer without HOA.⁸⁹

Clinical Manifestations

Often HOA is asymptomatic, and sometimes it is the patient who notes the changes in the shape of the fingers. Symptomatic patients complain about a deep-seated pain in the lower extremity and over the long tubular bones, which is exacerbated by palpation. Large joint effusions are

common, and the synovial fluid is thick with few white blood cells.⁹⁰ Skin hypertrophy may be confined to the nail beds or involve the face or larger areas overlying the tubular bones or joints.

The most common and apparent clinical manifestation is digital clubbing. The bulbous deformity of the fingertips is accompanied by a convex nail (watch-crystal nail). The skin around the nail bed becomes shiny and thin with disappearance of the creases (Figure 102-6). Palpation of the base of the nail bed yields the sensation of a “floating” nail within the soft tissue. Cases of advanced clubbing can be identified easily. Several methods were developed, however, to diagnose early phases of the condition. Among those techniques, the digital index and the phalangeal depth ratio have been most widely used.^{91,92} The digital index measures the ratio between the circumference at the level of the nail bed and the circumference at the distal interphalangeal joint of the 10 fingers. The sum of ratios greater than 10 suggests clubbing. The phalangeal depth ratio measures the ratio between the depth of the distal phalanx and the depth of the distal interphalangeal joint of the index finger. A ratio greater than 1 is considered abnormal.

There are no specific laboratory tests to diagnose HOA. Radiographs of the fingers and toes may show acro-osteolysis, and periostitis manifest by cortical thickening of long bones is often observed. The process may involve few or multiple sites and can be regular or irregular in appearance. Characteristically, there is no reduction in joint space or erosions. Radioisotope bone scanning can be useful for diagnosis and for evaluating the extent of the process. Increased uptake can be seen in the cortex of long bones sometimes in the form of splints (Figure 102-7).

Treatment Considerations

Asymptomatic cases need no treatment. NSAIDs are sometimes useful in symptomatic patients. Case reports have suggested that significant pain relief was observed after treatment with octreotide or pamidronate.^{93,94} In secondary cases of HOA, all features and symptoms promptly regress with successful treatment of the primary disease such as correction of a heart malformation, removal of tumors, and therapy of infective endocarditis or inflammatory bowel disease. The role played by VEGF in the pathogenesis of HOA suggests that treatment with VEGF inhibitors might improve the symptoms of this condition.⁹⁵

SAPHO SYNDROME

SAPHO syndrome is a chronic inflammatory disorder, often relapsing, of unknown etiology. The term SAPHO was coined in order to include several associated clinical manifestations: synovitis, acne, pustulosis, hyperostosis, and osteitis.⁹⁶ The most common sites of bone involvement are in the anterior chest wall, mainly the clavicles, sternum, and sternoclavicular joint.⁹⁷ The syndrome has been associated with a variety of skin lesions such as acne conglobata, acne fulminans, palmoplantar pustulosis, and psoriasis. The condition is uncommon with an estimated prevalence of 1 in 10,000, but the exact prevalence is difficult to establish in the absence of validated diagnostic or classification criteria. Furthermore, it is presumed that the prevalence of SAPHO syndrome is underestimated, in particular with mild or absent skin manifestations.⁹⁸

Etiology and Pathogenesis

The etiology of SAPHO syndrome is unknown. Infectious etiology has been proposed on the basis of the isolation of *Propionibacterium acnes*, a slowly growing anaerobic microorganism often found in acne, from sternal osteosclerotic lesions.⁹⁹ It has been postulated that *P. acnes* might act directly inducing bony erosions by chronic indolent inflammation. It has also been suggested that *P. acnes* may trigger complement activation and promote production of

interleukin (IL)-1, IL-8, and tumor necrosis factor (TNF), which contribute to both humoral and cellular proinflammatory responses. An imbalance between proinflammatory and anti-inflammatory mediators has been also suggested to contribute to the inflammatory response and the subsequent damage.^{100,101}

Genetic susceptibility has not yet been found. No associations with HLA-B27, other alleles often associated with psoriatic arthritis, or other candidate genes have been identified.^{97,102,103}

Inconsistencies in the reported prevalence of common autoantibodies encountered in autoimmune diseases, in patients with SAPHO syndrome, preclude at present any firm evidence for their role in the development of this condition.¹⁰⁴ It has been suggested that the increased association of SAPHO syndrome with inflammatory bowel disease might link SAPHO to the seronegative spondyloarthropathies, but this view has not yet been confirmed.^{97,105}

Clinical Manifestations and Imaging Findings

SAPHO syndrome is characterized by the combination of skin and osteoarticular manifestations. The skin manifestations include palmoplantar pustulosis, severe acne, suppurative hidradenitis, and at times psoriasis. The skin manifestations can anticipate or follow the osteoarticular manifestations, at times by many years.^{97,106,107}

The osteoarticular features of SAPHO syndrome are hyperostosis, aseptic osteitis occasionally involving the adjacent joints, and synovitis. The early histologic findings of the bone lesions are similar to those of osteomyelitis with periosteal bone formation. Subsequently the lesions evolve into chronic inflammation with preponderance of mononuclear infiltrate, and only in the late phases prominent marrow fibrosis, sclerosis, and enlarged bone trabeculae ensue.¹⁰⁸

The most characteristic clinical manifestation is pain in the anterior chest wall due to common involvement of the clavicles, sternum, and the sternoclavicular joints.^{97,107} Other common sites of involvement in the axial skeleton are the vertebral bodies with vertebral sclerosis, hyperostosis, spondylodiskitis, nonmarginal syndesmophytes, at times with anterior bridging; the bone adjacent to the sacroiliac joint; and the pubic symphysis.^{105,109} Extraplural involvement is infrequent but may be observed in the form of osteitis involving the tibia, femur, or mandible and with arthritis involving knees, hips, ankles, or small joints of hands and feet.^{97,105,110} The diagnosis is highly suspected in cases with usually sterile, multifocal, recurrent osteomyelitis, with or without cutaneous lesions; arthritis associated with palmoplantar pustulosis, pustular psoriasis, or severe acne; and osteitis associated with severe acne, palmoplantar pustulosis, or pustular psoriasis.¹⁰⁷

Laboratory investigations may reveal moderately elevated erythrocyte sedimentation rate (ESR) or acute phase reactants such as CRP and C3 and C4. These findings may reflect the inflammatory nature of the condition but are less reliable than in other inflammatory rheumatic disorders.^{97,105}

The diagnosis is usually established on the correlation between the clinical presentation and imaging findings. Bone scintigraphy is sensitive to detect the anterior chest

wall involvement demonstrating the characteristic “bull’s head” sign.¹¹¹ Plain radiographs may detect advanced lesions, but computed tomography (CT) scan enhances the ability to detect these lesions in particular in flat bones. Radiographic studies of the anterior chest lesions show osteitis in the form of osteosclerosis with homogeneous fibrillary pattern, hyperostosis in the form of periosteal reaction, and cortical thickening leading to bone hypertrophy. These lesions with eventual erosive arthritis (due to either primary arthritis or extension of the adjacent osteitis), classically involve the sternoclavicular joint, the upper costosternal and manubriosternal junctions. The spine, being involved in about a third of the patients, presents with similar radiographic appearance with vertebral sclerosis, hyperostosis, spondylodiskitis, nonmarginal asymmetric syndesmophytes, and at times hyperostosis in the form of osseous bridging along the anterior aspect of the spine.¹⁰⁶ In a recent magnetic resonance imaging (MRI) study, corner vertebral erosions were a consistent finding, frequently with involvement of the vertebral end plates and at times adjacent vertebra.¹¹² The meaning of these findings has not yet been fully elucidated, and further studies are necessary. Enteseal ossifications, osteitis, osteosclerosis, and periosteal new bone formation have all been reported with variable frequency in long bones.

Treatment

Nonsteroidal anti-inflammatory drugs (NSAIDs) are usually the first line of treatment and may improve the symptoms. However, they often fail to control the disease and additional therapy with corticosteroids and other modalities is required.^{97,113} Several empiric therapeutic approaches have been reported in SAPHO including NSAIDs, corticosteroids, bisphosphonates, sulfasalazine, methotrexate, antibiotics, and anti-TNF agents.¹¹³ Second-line drugs including methotrexate, cyclosporine, sulfasalazine, and leflunomide have been tried with mixed results.^{105,113,114} Treatment with antibiotics, usually azithromycin, has been reported to be beneficial in patients with SAPHO syndrome. However, many patients were also treated with other disease-modifying antirheumatic drugs and the response faded after discontinuation of the antibiotic. It is not clear whether the response to the antibiotic, though transitory, is due to its antibacterial or anti-inflammatory effect.¹¹⁵ In recent years, bisphosphonates, in particular pamidronate have been reported to elicit a good or partial response in the majority of patients affected by SAPHO syndrome.¹¹⁶ It seems that beyond their ability to prevent bone resorption, bisphosphonates are capable of suppressing the production of proinflammatory cytokines such as IL-1, TNF, and IL-6.¹¹⁷ Treatment with TNF blockers has emerged as an effective therapy in SAPHO syndrome. The results appear to be less spectacular than in other seronegative spondyloarthropathies and may be hampered by relapse of the skin manifestations.^{118,119}

KEY POINTS

Osteonecrosis affects younger patients more often than osteoarthritis and has significantly greater long-term morbidity.

Corticosteroids constitute the most common cause of nontraumatic osteonecrosis.

The femoral head is the most common site of osteonecrosis.

Bisphosphonate use is associated with osteonecrosis of the jaw.

The final common pathway in the pathogenesis of osteonecrosis is disruption of blood supply to a segment of bone.

Abnormalities in lipid metabolism, bone homeostasis, regulation of apoptosis, coagulopathies, and oxidative stress may play a role in the pathogenesis of osteonecrosis.

Magnetic resonance imaging is currently the optimal test for early diagnosis and identification of the extent of osteonecrosis.

Nonsurgical treatment of osteonecrosis does not change the natural history of the disease.

Although there are many variations on surgical treatment of femoral head osteonecrosis, most patients eventually require total hip arthroplasty.

Knowledge of risk factors and early detection are crucial to the successful management of osteonecrosis.

Due to the lack of successful treatment options, new modes focus on prevention of osteonecrosis.

Osteonecrosis literally means “bone death” (*ossis* [Latin] = bone; *necrosis* = killing or causing to die). Other synonyms include avascular necrosis, ischemic necrosis of bone, aseptic necrosis, and subchondral avascular necrosis. The term *osteonecrosis dissecans* is sometimes used synonymously with osteonecrosis, although, strictly speaking, it is a consequence of osteonecrosis involving dessication of bone leading to fracturing or cracking of bone. The concept of bone death was first described by Hippocrates,¹ but the first clinical description of osteonecrosis was a case of sepsis-induced bone death described by Russell in 1794.² It was almost a century later that bone death was described to occur in the absence of infection.³ The first report of osteonecrosis in a deep sea diver appeared in 1936.⁴ The pathogenesis of osteonecrosis is complex, but whatever the mechanism, bone death ultimately occurs as a result of complete or partial disruption of the delivery of oxygen and/or nutrients to the bone and surrounding tissues. It is likely that multiple molecular mechanisms may be simultaneously in play in order for osteonecrosis to occur.^{5,6}

EPIDEMIOLOGY

The prevalence of osteonecrosis is unknown, but it is estimated that there are 10,000 to 20,000 new patients diagnosed per year in the United States. Osteonecrosis occurs in 15% to 80% of patients with femoral neck fractures.⁷ Ten percent of the 500,000 hip replacements done in the United States each year are thought to be for osteonecrosis.⁸ The disease primarily affects men, with a notable exception for osteonecrosis associated with systemic lupus erythematosus, which has a significant female predominance. Osteonecrosis primarily occurs in the third to fifth decade of life.⁹ As a result of this age distribution, long-term morbidity can be significant because most hip replacements have a finite period of viability.

ETIOLOGY

Osteonecrosis has been linked to numerous conditions (Table 103-1). The strength of a causal relationship varies greatly, and in some cases only case reports have been published. The most common cause of nontraumatic osteonecrosis is corticosteroid use, which was first described in 1957.¹⁰ Although other adverse effects of corticosteroids are perhaps better known, osteonecrosis of the femoral head is one of the serious complications.

In a 1998 study, in which the investigators reviewed associations in 2500 to 3300 cases of nontraumatic osteonecrosis, corticosteroid use was present in 34.7% of cases. Alcohol use was found in 21.7% of the cases, and the remainder was idiopathic. Although the risk of developing osteonecrosis with corticosteroid use is small, the severity of the adverse event and the high morbidity associated with osteonecrosis make this an important complication to consider when starting a patient on corticosteroids.

Studies have attempted to determine the duration of use and the dosages of corticosteroids necessary to precipitate osteonecrosis. There are several forms of corticosteroids of differing potency and half-life, and dosages and duration of use vary between studies, so any conclusions about a “safe” dose of corticosteroids are wrought with potential confounding variables and errors. In one study of 20 patients diagnosed with stage 1 osteonecrosis by magnetic resonance imaging (MRI), the interval between the use of steroids and diagnosis ranged from 1 to 16 months.¹¹ The cumulative dose of steroids in this study ranged from 1800 to 15,505 mg (mean, 5928 mg) of prednisolone or the equivalent. In other studies cumulative doses of steroids associated with osteonecrosis ranged from 480¹² to 4320¹³ mg of dexamethasone dose equivalence. A recent paper by Powell and colleagues¹⁴ attempted to collectively analyze the available

literature to derive maximum safe levels for duration, maximum daily dose, and average daily dose of corticosteroids. The study confirmed that many other confounding variables affect the development of osteonecrosis, making analysis of dose-response risk for an isolated association difficult. Nonetheless, corticosteroid-induced osteonecrosis is

dependent on dosage and the risk factor is higher with the long-acting steroids and with parenteral usage.

Additional host-inherent risk factors also play a role in susceptibility. The incidence of osteonecrosis in a group of patients receiving glucocorticoid replacement therapy for primary or secondary adrenal insufficiency was 2.4%. In a study of renal transplantation patients, the 26 patients who developed osteonecrosis had a higher cumulative oral dose of prednisone after 1 and 3 months compared with 28 control transplant patients who did not develop osteonecrosis.¹⁵ A separate study estimated the incidence of osteonecrosis in renal transplant patients to be 5%.¹⁶ There is no evidence to consistently link the use of topical, inhaled, or nasal corticosteroids to osteonecrosis. The evidence for an association between osteonecrosis and intramuscular or intra-articular corticosteroids is limited to case reports.¹⁷ Parenteral use poses a higher risk because of rapid absorption and longer half-life of the drugs used.

Bisphosphonate-induced osteonecrosis of the jaw is particularly interesting because of the intended use of bisphosphonates on bone diseases.¹⁸⁻²⁰ There has been a link between cigarette smoking and osteonecrosis, with smokers having a threefold higher relative risk for developing osteonecrosis, independent of all other factors.^{21,22}

The association between osteonecrosis and alcohol consumption was first described in 1922.²³ A study of patients with idiopathic osteonecrosis revealed that the risk of osteonecrosis increased with increasing daily consumption of alcohol.²¹ The subjects were divided into three groups on the basis of their alcohol consumption of less than 400 mL/week, 400 to 1000 mL/week, and greater than 1000 mL/week, and the relative risk of osteonecrosis, independent of corticosteroid use or smoking, was 3-fold, 10-fold, and 18-fold, respectively, when compared with hospital controls. Liver damage was also found unnecessary for the development of osteonecrosis in alcohol-consuming patients, although elevated liver enzymes may be present.²⁴ The incidence of osteonecrosis in patients who received treatment for alcoholism was 5.3%. The femoral head was again the most common site (82 of 92 lesions), with the other 10 sites involving the humeral head.²⁵

Musculoskeletal conditions can lead to osteonecrosis in children. Legg-Calvé-Perthes disease was first described in children between 3 and 12 years of age in 1910.²⁶⁻²⁸ Femoral head osteonecrosis is a feature of this disease and has been linked to trauma,^{29,30} congenital hip dislocation,³¹ and transient synovitis.³² Bilateral involvement is common, and associated clinical manifestations include abnormal growth and stature,^{33,34} delayed skeletal maturation,³⁵ disproportionate skeletal growth,³³ congenital anomalies,³⁶ and abnormal hormone levels.^{37,38} Children with acute lymphoblastic leukemia can develop osteonecrosis^{39,40} as well, but this may be a result of steroid use. An additional risk factor for this cohort of patients is high body mass index.⁴¹

Osteonecrosis has also been associated with metabolic disorders and in pregnancy. Diagnosis is often delayed until months after delivery. Women who develop osteonecrosis in pregnancy tended to have a small body frame and a large weight gain.⁴²

Hematologic conditions have been associated with osteonecrosis. The long-term morbidity of osteonecrosis in patients with sickle cell anemia is dismal.⁴³ Common

deformities include decreased mobility, abnormal gait, and leg-length discrepancy.⁴⁴ Osteonecrosis in hemophilia patients has been reported, but no statistically reliable causal link can be established.⁴⁵⁻⁵⁰

Dysbaric osteonecrosis was first described in construction workers in the Elbe tunnel exposed to high-pressure environments.⁵¹ The prevalence of dysbaric osteonecrosis is 4.2% in divers and 17% in compressed air workers.⁵² Patients with dysbaric osteonecrosis may have more than one lesion, and common sites besides the femoral head include the tibia and the humeral head and shaft. The condition is not related to decompression sickness, and although proper decompression procedures can reduce “the bends,” they do not have any effect on the development of osteonecrosis, which can occur months or years after the last exposure to high-pressure environments.

Osteonecrosis has also been associated with a number of infectious diseases including severe acute respiratory syndrome (SARS). Many patients who contracted SARS in the early 2000s received treatment with corticosteroids, and some subsequently developed osteonecrosis.⁵³ The incidence of osteonecrosis appears higher in this group of patients compared with patients with other conditions who were treated with corticosteroids.⁵⁴ Chan and colleagues⁵⁵ reported five children with SARS treated with corticosteroids who developed osteonecrosis.

CLINICAL FEATURES

The primary presenting symptom in osteonecrosis is pain. In osteonecrosis of the femoral hip, the pain is located in the hip joint but may radiate to the groin, anterior thigh, or knee. The severity of the pain can vary, depending on the size of the infarct and whether the onset of disease is insidious or sudden. In trauma, where there is sudden and severe disruption of blood flow, and in Gaucher's disease, dysbarism, or hemoglobinopathy, where the infarcts are large, pain can be intense and sudden. In other conditions where the onset is more insidious, the pain can follow a gradual and slow incremental progression. The pain of osteonecrosis is usually increased with use of the joint, but in advanced disease the pain can be persistent at rest. Limitation of range of motion is progressive and is usually a late symptom, except when resulting from accompanying pain. The risk of developing osteonecrosis of the contralateral hip when one side is affected ranges from 31% to 55%.

In addition to the femoral head, osteonecrosis can affect other sites including the humeral head,⁵⁶⁻⁵⁹ femoral condyles⁶⁰⁻⁶³ and proximal tibiae,^{61,64-66} wrists and ankles,⁶⁷ bones of the hands and feet,⁶⁸ the vertebrae,⁶⁹⁻⁷¹ jaw,⁷²⁻⁷⁵ and bony structures of the face.⁷⁶ Osteonecrosis of the humeral head is the second most commonly seen location, and pain is usually in the shoulder and associated with reduced range of motion and weakness. Pain in the ankle is the main presenting symptom in nontraumatic osteonecrosis of the talus, and in some cases, the disease had already progressed to Ficat and Arlet stage 3 by the time of presentation of pain.⁶⁷ Kienböck's disease involves osteonecrosis of the lunate. Patients present with pain in the radiolunate joint, along with weakness and limitation of motion. Kienböck's disease appears to be related to manual labor. Soccer players have been reported to develop osteonecrosis of the foot,⁷⁷

Table 103-2 Modified Steinberg Staging Systems for Osteonecrosis

Stage	Radiographic Appearance	Reversible
I	Normal radiographs, but abnormal bone scan or magnetic resonance image	Yes
II	Lucent and sclerotic changes	Yes
III	Subchondral fracture without flattening	No
IV	Subchondral fracture with flattening or segmental depression of femoral head	No
V	Joint space narrowing or acetabular changes	No
VI	Advanced degenerative changes	No

and football players may be prone to developing osteonecrosis of the hip.⁷⁸

The Ficat and Arlet method of staging osteonecrosis consists of four stages. Stages 1 and 2 are reversible, whereas stage 3 (subchondral collapse) and stage 4 (joint space narrowing and destruction of cartilage) are irreversible. The Marcus staging system consists of six stages, in which the first two are reversible and the subsequent four are irreversible. The modified Steinberg staging system is based on the Marcus system and also consists of six stages. Each stage is further divided into three subclasses on the basis of the extent of femoral head involvement. Subclass A involves less than 25%; B involves 26% to 50%, and C involves greater than 50%.

Table 103-2 shows the Modified Steinberg system for staging osteonecrosis. The Association of Research Circulation Osseous (ARCO) has proposed a modification to the Ficat and Arlet system, adding a stage 0 or patients with negative imaging studies but who are at risk for developing osteonecrosis. In addition, stages 1 and 3 are further stratified to take into account lesion size, location, and extent of collapse.⁷⁹ In 2001 the Japanese Ministry of Health, Labor and Welfare proposed revising criteria for the diagnosis and staging of osteonecrosis of the femoral head.⁸⁰ Diagnostic criteria included the following: (1) collapse of the femoral head without joint space narrowing or acetabular abnormality on plain radiograph, (2) demarcating sclerosis in the femoral head without joint space narrowing or acetabular abnormality, (3) “cold in hot” on bone scans, (4) low-intensity band on T1-weighted MRI, and (5) trabecular and marrow necrosis on histology. If a patient fulfills two of the five criteria, the diagnosis is established. The working group also proposed four types of lesions on the basis of extensiveness and defined stages of disease on the basis of diagnostic imaging.

Bone Marrow Edema

Bone marrow edema is a common observation in osteonecrosis and is frequently accompanied by vascular congestion. Bone marrow edema is not specific for osteonecrosis and may be seen in many musculoskeletal disorders including osteomyelitis, osteoarthritis, occult intraosseous fracture, stress fracture, osteoporosis, and sickle cell crisis.

A specific syndrome known as *bone marrow edema syndrome* has been described and was initially thought to be a

precursor to osteonecrosis, but it is now believed to be a separate entity. Bone marrow edema is a transitory, self-limiting condition typically seen in middle-aged men and in women in their third trimester of pregnancy. Patients complain of pain, limited range of motion, and an abnormal gait. Osteopenia is detected on conventional radiographs, and MRI confirms this with a low signal on T1-weighted images and a high signal on T2-weighted images. The three phases of bone marrow edema syndrome include an initial phase lasting about 1 month, followed by a plateau phase lasting 1 or 2 months, and finally a regression phase lasting for an additional 4 to 6 months.⁸¹ Subchondral fractures do not occur. Biopsy specimens obtained in the initial phase show diffuse interstitial edema, fragmentation of fatty marrow cells, and increased new bone formation.⁸²

A study of 24 cases of bone marrow edema syndrome of the knee showed that although migrating bone marrow edema occurred in a third of patients at a 5-year follow-up, the patients were asymptomatic and MRI signal alterations had resolved. Biopsy specimens of affected bone were obtained using arthroscopic surgery and core decompression, and histology revealed areas of bone marrow edema and vital trabeculae covered by osteoblasts and osteoid seams. None of the cases progressed to osteonecrosis.⁸³

Bisphosphonates and Osteonecrosis of the Jaw

Bisphosphonate is a class of drug used to treat osteoporosis and diseases where bone is not formed adequately. Bisphosphonates are composed of two forms, and osteonecrosis appears to occur in association with nitrogen-containing bisphosphonates. The mechanism of action of bisphosphonate-induced osteonecrosis of the jaw appears to parallel that of glucocorticoids, with derangement in lipid metabolism, bone homeostasis, and apoptosis of bone cells. It is interesting that the jawbone seems to be the most vulnerable bone in bisphosphonate-induced disease, as opposed to the femoral head in most other associations or causes of osteonecrosis. This may be because of the high bone turnover rate in the jaw or because bisphosphonates exert their action on not only bone but also many elements of the surrounding tissue including fibroblasts and blood vessels.

PATHOGENESIS

Anatomic Considerations in Trauma-Related Osteonecrosis

The femoral head is the most common site of osteonecrosis. An understanding of the anatomy of the femoral head may help to explain why that is the case. Three arterial networks supply the femoral head and neck. The extracapsular arterial ring consists of the lateral femoral circumflex artery and the medial femoral circumflex artery, which arise from the profunda femoris. The medial femoral circumflex artery and its branches supply most of the blood to the head and neck of the femur. The lateral femoral artery winds anterolaterally, and the medial femoral artery winds posteromedially around the neck of the femur, ultimately anastomosing with each other at the superolateral aspect of the femoral head. The lateral femoral circumflex artery and the medial femoral

circumflex artery further anastomose with the superior and inferior gluteal branches of the internal iliac artery, providing collateral circulation between the femoral artery and the internal iliac artery. Small vessels known as *retinacular arteries*, ascending cervical branches of the extracapsular ring, form an intra-articular ring at the level of the cartilage. Epiphyseal arterial branches arise from this ring and penetrate the head and neck of the femur including the epiphyses. The artery of the ligament of the head of the femur is a branch of the obturator artery and may be the sole supplier of blood to the proximal fragment of the head.

Some of these anatomic features may render the femoral head particularly vulnerable to ischemia. The retinacular arteries are believed to supply 80% of the femoral epiphysis. Compromising this critical vascular system may lead to osteonecrosis originating in the anterosuperior aspect of the femoral head, as indicated by angiographic studies in early osteonecrosis in which these arteries are not visualized. A schematic of the blood supply to the femoral head is shown in Figure 103-1.

Histologically, after an infarct, a rim of bony thickening or sclerosis begins to form at the margins of the infarcted area. If the necrotic lesion is within the weight-bearing region of the femoral head, subchondral fractures follow. With repeated microfractures and continued weight bearing, the original fracture cannot heal completely and new fractures appear. The secondary fracture propagates along the junction between subchondral bone and the necrotic segment. As time goes on, the femoral head becomes flattened and eventually collapses. A nonspherical head articulating with the acetabulum produces friction and erosion and loss of cartilage. The cycle repeats itself, and the structure of the joint deteriorates, leading to degenerative changes and eventual total joint destruction.⁸⁴

Nontraumatic Osteonecrosis

Disruption of the blood supply to the femoral head can occur through a number of different mechanisms. In

Figure 103-1 Schematic of the blood supply of the femoral head.

Table 103-3 Proposed Mechanism of Disease of Common Conditions Associated with Osteonecrosis

Associated Condition	Mechanism of Osteonecrosis							
	Apoptosis	Osteoblast/ Osteoclast Homeostasis	Lipid Abnormalities	Coagulation Abnormalities	Oxidative Stress	Parathyroid/ Calcium Imbalance	Vascular Plugging	Vasoactive Substances
Corticosteroids	X	X	X	X	X			X

Renal transplantation	X	X		X		X		
Dialysis						X		
Sickle cell disease							X	

traumatic osteonecrosis of the femoral head, the cause of this disruption is often viewed as completely mechanical and appears to be easily understood. But there may be an additional component to the disruption that is related to the immunologic and inflammatory changes that occur in damaged bone tissue and surrounding soft tissues.

The immunologic changes occurring in nontraumatic osteonecrosis may help explain why corticosteroids are particularly dangerous to the integrity of the blood supply of the femoral hip. Some have likened osteonecrosis to “coronary disease” of the hip^{85,86} and propose that the same mechanisms that cause ischemia of the myocardium may also cause ischemia of the femoral head (Table 103-3).

Mechanical and Vascular Considerations

In Legg-Calvé-Perthes disease, obstruction to venous drainage elevates intraosseous pressure and consequently elevates intra-articular pressures. In a study of patients with Legg-Calvé-Perthes disease, bone scintigraphy using Tc99m methylene diphosphonate (Tc99m MDP) was employed to measure arterial and venous flow in the diseased hip. Although arterial flow was normal, there was significant disruption in venous drainage.⁸⁷ This disturbance was reproduced in a dog model in which injection of silicone was used to obstruct venous flow distal to the hip.⁸⁸ Ischemia resulted from the obstruction to venous drainage, leading to a cessation of endochondral ossification in the preosseous epiphyseal cartilage and the physeal plate. Widening of the joint space ensued, followed by revascularization of the epiphysis and deposition of new immature bone. A weakened or unstable femoral epiphyseal plate resulted, and the subchondral bone became prone to segmental collapse and fracture.⁸⁹

The pathologic mechanism of dysbaric osteonecrosis is unclear. The most intuitive explanation is that formation of gas bubbles causes arterial occlusion and ischemia. However, the true mechanism may not be quite so simple. Multiple other factors might contribute to the disease including thromboembolic events such as platelet aggregation, erythrocyte clumping, lipid coalescence, intraosseous vessel compression as a result of extravascular gas bubbles, formation of fibrin thrombi, and narrowing of arterial lumina owing to myointimal thickening caused by gas bubbles. The interaction between gas and blood can lead to the formation of vessel-occluding substances. All of these events can lead to redistribution of blood flow.

The increased vulnerability of bone to compression disorders has been explained by several factors including the relative rigidity of bone and inability to absorb increased gas pressure, inherent poor vascularization, and gas supersaturation of fatty marrow.⁹⁰ A sheep model of dysbaric osteonecrosis has been developed. Exposure to compressed air at pressures of 2.6 to 2.9 atmospheres for 24 hours results in extensive bone and marrow necrosis. The authors proposed that the initial event involving elevated intramedullary pressures leads to the formation of nitrogen gas bubbles in the fatty marrow of the long bones. Radiography shows medullary opacities and endosteal thickening. Later, neovascularization of previously ischemic fatty marrow occurs, followed by new bone formation. Osteonecrosis occurs in subchondral cortical bone with marrow fibrosis and osteocyte loss.⁹¹

Changes in the vasculature, through injury or inflammation from other diseases, may in turn lead to a compromise in blood flow. Examples include structural damage to arteriolar walls, degeneration of the tunica media, smooth muscle cell necrosis, and disruption of the internal elastic lamina. These changes can lead to eventual hemorrhagic infarction, which was observed in a study of 24 core biopsy specimens from osteonecrotic femoral heads. The changes did not occur in 11 femoral heads with osteoarthritis.⁹²

Osteoimmunology

Although bone marrow is a critical component of the immune system, bone matrix is often perceived to be static scaffolding that functions primarily to support the musculoskeletal system. It is now known that, in fact, bone matrix is a dynamic tissue that is constantly replacing itself. It is estimated that about 10% of a person's bone is replaced every year. Diseases such as osteopetrosis and osteoporosis are a result of a dysfunction in the balance between bone deposition and bone resorption. The factors that regulate this homeostasis include cells of the bone matrix, immune cells, signaling molecules, cytokines and chemokines, and vitamins. Some of these regulatory factors may be present on both bone cells and immune cells, often serving different functions, thereby providing a link between the immune system and bone. Osteonecrosis, in fact, may be linked to such an imbalance in bone homeostasis. Immune factors may affect surrounding soft tissue as well, contributing to the development of osteonecrosis. The study of immune regulation of bone in osteonecrosis may

encompasses many of the previously proposed mechanisms of osteonecrosis including apoptosis, oxidative stress, and genetic predisposition.

Immune factors involved in bone homeostasis include receptor activator of NF κ B (RANK) and its ligand (RANKL), IL-1, IL-6, IL-10, TGF- β , TNF, CD80, CD86, CD40, macrophage colony-stimulating factor (M-CSF), NFATc, and vitamin D. (See Table 103-4 for roles and function.) Many of these factors can be categorized into one of two categories, those with the overall effect of inducing osteoclastogenesis and those that inhibit osteoclastogenesis. In addition, factors involved in cell survival and apoptosis such as Blimp-1 and Bcl6 may also play a role. RANKL is expressed on osteoblasts and is critical for the differentiation and proliferation of osteoclasts. Because transcription of factors involved in the regulation of bone homeostasis is often influenced by glucocorticoids, this may begin to explain why steroids may be associated with osteonecrosis.

The action of glucocorticoids is mediated by the glucocorticoid receptor, which is present on many cell types

including osteoclasts, osteoblasts, osteocytes, and cartilage. Binding of glucocorticoids to its receptor leads to the anti-inflammatory activity known to be a function of steroids. One mechanism by which this anti-inflammatory effect is mediated is by transcription of genes that inhibit the synthesis of inflammatory mediators.

Osteoblast/Osteoclast Balance

Any disturbance in the normal homeostasis between bone deposition and bone resorption can lead to bone disease. Moreover, defective bone deposition or bone resorption in which new bone is formed in an aberrant manner can lead to disease. Alcohol can affect the ability of mesenchymal stem cells to differentiate into osteogenic lineages. The bone marrow in the proximal head of femurs was isolated during hip replacement surgery from 33 patients with either femoral neck fractures or alcohol-induced osteonecrosis. The cells from femurs of patients with alcohol-induced osteonecrosis showed a reduced ability to differentiate into

Table 103-4 Role and Function of Immune Factors in Osteoimmunology

Immune Factor	Ligand	Cellular Source	Function in Bone Homeostasis	OC	Immune Function
RANK	RANKL	Osteoclasts, dendritic cells	Upon binding to RANKL, signals differentiation into osteoclast	↑	RANKL-RANK binding leads to dendritic cell activation
RANKL	RANK	Osteoblasts, T helper cells	Activation of osteoclasts. Overproduction can result in RA or PA	↑	Dendritic cell maturation
OPG	RANKL		Decoy receptor for RANKL	↓	
M-CSF	CSF-1 receptor	Osteoblasts, macrophages, bone fibroblasts, stromal cells	Stimulates osteoclastogenesis	↑	Influences hematopoietic stem cells to differentiate into macrophages
TNF	TNF receptor	Macrophages, lymphocytes, mast cells, and many others	Stimulates osteoclastogenesis	↑	Influences multiple signaling pathways, including NF κ B, death signaling and MAP kinase pathway
TGF- β	TGF- β receptor	Multiple cell lines	Induction of apoptosis	↑	Regulatory role, blocks activation of lymphocyte- and monocyte-derived phagocytosis
Blimp-1	Bcl6 promoter	Plasmablasts, plasma cells	Binds to Bcl6 promoter, suppression expression	↑	Inhibits Tfh cell differentiation in mice ²²¹
Bcl-6	?	Germinal center B cells	Inhibits osteoclastogenesis	↓	Stimulates Tfh cell differentiation in mice
IL-1	IL-1R	Macrophages, monocytes, fibroblasts, dendritic cells	Directly activates RANK signaling to promote osteoclastogenesis ²²²	↑	Proinflammatory cytokine, endogenous pyrogen
IL-6	IL-6R	Osteoblasts	Activation of osteoclastogenesis	↑	Proinflammatory cytokine
IL-10	IL-10R α	Monocytes, lymphocytes	Suppress bone resorption	↓	Anti-inflammatory cytokine, blocks NF κ B activity, regulatory cytokine
Vitamin D	VDR	Osteoblast, monocyte/macrophage	Facilitate adhesion of osteoclast precursor to osteoblast ²²³	↑	Cell proliferation and differentiation
Estrogens	Estrogen receptor	Ovarian follicle cells	Reduces osteoclast IL-1 responsiveness and cell survival, ²²⁴ stimulates osteoprotegerin	↓	Angiogenesis, endothelial healing
IL-17	IL-17R	T cells	May have opposing roles of bone protection and bone loss ²²⁵	↑↓	Proinflammatory cytokine
IL-18	IL-18R	Macrophages	Inhibits TNF-mediated osteoclastogenesis in a T cell-independent manner	↓	Proinflammatory cytokine, works in synergy with IL-12

Examples of some of the factors involved in bone metabolism. In addition to the factors listed, there are many others that play a role, either by themselves or in conjunction with other factors. The factors listed may have many other functions. Only select functions are listed.

Bcl6, B cell lymphoma 6 protein; Blimp, B lymphocyte-induced maturation protein 1; CSF-1, colony-stimulating factor 1; OC, osteoclastogenic; OPG, osteoprotegerin; PA, psoriatic arthritis; RA, rheumatoid arthritis; RANK, receptor activator for NF κ B; RANKL, receptor activator for NF κ B ligand; Tfh, T follicular helper cell; TGF- β , transforming growth factor beta; TNF, tumor necrosis factor; VDR, vitamin D receptor.

osteoblasts.⁹³ A subsequent study compared the mesenchymal stem cells from patients with hip osteoarthritis, idiopathic osteonecrosis, and nontraumatic osteonecrosis associated with steroid or alcohol use. In idiopathic and alcohol-induced osteonecrosis, the ability of mesenchymal stem cells to differentiate into osteoblasts was decreased, but in steroid-induced osteonecrosis, it was elevated, although not to a statistically significant level. The adipogenic differentiation ability was similar in all four groups.⁹⁴

In rats fed a diet of alcohol and glucose, lower bone mineral content and density were detected compared with controls. In hamsters, alcohol led to thinning of the trabeculae of the distal part of the femur. Cytologic effects included mitochondrial swelling in osteoblasts and osteocytes. Partial osteonecrosis of the femoral head was detected in Merino sheep that were injected with ethanol. In humans, alcohol causes increased plasma calcium levels, decreased osteocalcin and circulating parathyroid hormone levels, reduced serum calcitriol, reduced bone volume, and increased osteoclast number.

Alterations in osteoblast function may also contribute to the pathogenesis of osteonecrosis. In one study, osteoblastic cells were obtained from bone biopsy specimens from the intertrochanteric region of the femur and of the iliac crest of 13 patients with osteonecrosis and 8 patients with hip osteoarthritis. Cell replication was measured on the basis of proliferation rate in secondary culture. Levels of alkaline phosphatase activity, collagen synthesis, and the sensitivity to 1,25-dihydroxyvitamin D₃ were measured. The results indicated that although differentiation was not affected, the proliferation rate of osteoblastic cells was reduced in samples obtained from the patients with osteonecrosis compared with patients with osteoarthritic hips.⁹⁵

Apoptosis and Osteonecrosis

Glucocorticoids can also act via its action on apoptosis of immune and bone cells. When mice were administered prednisolone for 27 days, increased metaphyseal apoptotic activity of both osteoblasts and osteoclasts were noted.⁹⁶ The result was decreased bone turnover, density, and formation; increased formation of cancellous bone; and decreased trabecular width. The decreased bone turnover can be explained by the reduced osteoclast survival, and the reduction in trabecular width can be explained by a decrease in osteoblasts. An accumulation of apoptotic elements was also found in the region of the “fracture crescent” in the femurs of glucocorticoid-treated patients. On the other hand, glucocorticoids may also increase osteoclast survival, leading to increased bone loss. Clearly, the effect of osteoclast survival on bone disease is more complicated than at first glance, and it involves the interaction of the osteoclast with the osteoblast. Because osteoblasts are also responsible for osteoclast differentiation under the right circumstances, there exists a significant feedback system that maintains bone homeostasis.

Osteocyte death is also a feature of osteonecrosis. In a rat model, ischemia caused an induction in the expression of stress proteins, oxygen-regulated protein (ORP150) and hemoxygenase 1 (HO1). Induction of ischemia in these rates caused DNA fragmentation and the presence of apoptotic bodies in chondrocytes, bone marrow cells, and

osteocytes.⁹⁷ Both alcohol and corticosteroids can induce osteocyte apoptosis, possibly via lipid abnormalities.

Lipids and Osteonecrosis

The bone marrow of rabbits that were fed alcohol showed fatty infiltration of the liver and adipogenesis in the bone marrow. Increases in fat cell hypertrophy and proliferation, as well as a decrease in hematopoiesis in the subchondral head, were observed. Osteocytes contained triglyceride deposits, and there was an increase in empty osteocyte lacunae. Alcohol also primarily triggered differentiation of bone marrow stromal cells into adipocytes in a dose-dependent manner. Intracellular lipid deposits led to the death of osteocytes.

In corticosteroid-induced osteonecrosis, the alteration in lipid metabolism parallels that of alcohol-induced osteonecrosis. In both cases, fatty infiltration of osteocytes has been postulated to occur.⁹⁸⁻¹⁰⁰ Table 103-5 lists lipid-altering effects of corticosteroids and alcohol. In addition, interosseous venous stasis affects the interosseous microcirculation, which can lead to hemodynamic and structural changes in the femoral head. The resulting decrease in blood flow leads to osteonecrosis. In chickens treated with steroids, fatty infiltration of the liver and fat cell hypertrophy and proliferation in the femoral head occurred concurrently 1 week after the initiation of steroids. As in the case of alcohol-induced osteonecrosis, adipocytes contained triglyceride vesicles. In rabbits treated with steroids, it was found that interosseous pressure was increased and the size of bone marrow fat cells was larger than in control rabbits.¹⁰¹ A histologic study of acetabular and proximal femoral bone in osteonecrosis of the femoral head revealed that osteonecrosis is more extensive in corticosteroid-induced compared with alcohol-induced or idiopathic osteonecrosis.¹⁰² The reason for this is unknown.

In osteonecrosis of the jaw, bisphosphonates inhibit protein prenylation via inhibition of the enzyme farnesyl diphosphate synthase. The normal lipid metabolism of pathways that regulate cytoskeletal integrity and osteoclastogenesis such as Rho, Rac, and Ras is disrupted. This is one of the mechanisms by which bisphosphonates exert their intended action, but their ability to disrupt normal regulation of bone metabolism may instead lead to osteonecrosis.

Coagulation and Osteonecrosis

The hyperlipidemia, increased serum free fatty acids, and increased prostaglandins that are associated with alcohol-induced osteonecrosis may potentially trigger vascular

Table 103-5 Lipid-Altering Effects of Steroids and Alcohol

inflammation and coagulation. Other triggers for intravascular coagulation include atherosclerosis and arteriolar fibroid degeneration. Jones proposed that the progression of osteonecrosis from stage 1A to 1B is linked to an inability to clear procoagulants from blood or tissue.¹⁰³ He proposed that decreased clearance of procoagulants leads to persistent levels of tissue thromboplastin, leading to arteriolar thrombosis, vascular stasis, free fatty acid-induced endothelial damage, and hypercoagulability. Studies have shown that patients with osteonecrosis had a much higher frequency of having at least one and at least two abnormal coagulant levels compared with normal controls. Of patients with osteonecrosis, 82% had at least one abnormal procoagulant level, and 47% had at least two. In normal controls, only 30% had one abnormal procoagulant level and only 2.5% had two or more. The procoagulants measured included free protein S, protein C, lipoprotein A, homocysteine, plasminogen activator inhibitor, stimulated tissue plasminogen activator, anticardiolipin antibodies (IgM and IgG), and resistance to activated protein C.¹⁰⁴

In addition, both thrombophilia and hypofibrinolysis have been associated with osteonecrosis. Hypofibrinolysis leads to an increased likelihood of clot formation, and thrombophilia results in a decreased ability to lyse clots. This is yet another mechanism by which corticosteroids lead to osteonecrosis—high-dose steroids lead to increased plasma plasminogen activator inhibitor, decreased tissue plasminogen activator activity, and inhibition of the fibrinolytic pathway, thus leading to a higher risk for clot formation. There is an early indication that coagulation abnormalities may play a significant role in corticosteroid-induced osteonecrosis in SARS patients.^{105,106}

Oxidative Stress and Osteonecrosis

Alcohol consumption is associated with reduced superoxide dismutase activity. Alcohol has deleterious effects on muscle including increased oxygen free radical-related damage, reduced myocardial contractility, defective mitochondrial function, and increased tissue enzymes.¹⁰⁷ When rabbits were injected with methylprednisolone, elevations in 8-hydroxy-2'-deoxyguanosine, a marker of DNA oxidative injury, were observed.¹⁰⁸⁻¹¹⁰ This coincided with the development of osteonecrosis. A polymorphism in nitric oxide synthase, described later, was also associated with the development of osteonecrosis. This relationship between osteonecrosis and oxidative injury leads one to wonder if corticosteroid-induced osteonecrosis can be prevented or lessened in severity by simultaneous or prophylactic administration of antioxidants.

Nitric Oxide Synthase and Osteonecrosis

Glucocorticoids can cause derangements in vascular responsiveness to vasoactive substances such as nitric oxide. Endothelial nitric oxide synthase (eNOS) stimulates the production of nitric oxide. Nitric oxide regulates vascular "tension" by acting as a vasodilator, inhibiting mononuclear adhesion to endothelial cells and preventing platelet aggregation. A defect in this activity can lead to increased vascular resistance and disruption to downstream blood flow, resulting in osteonecrosis.¹¹¹

Multihit Hypothesis

Other proposed mechanisms involve endothelial cell injury,¹¹² abnormal angiogenesis and repair mechanisms,¹¹³ the effects of vasoactive substances,¹¹⁴ activity of hepatic cytochrome P450 3A4,¹¹⁵ and intramedullary hemorrhage.¹¹⁶ Multiple mechanisms may be simultaneously occurring. Kenzora was the first to introduce the concept of cumulative stress.¹¹⁷ Corticosteroid-induced osteonecrosis seems to occur with greater frequency in patients who have significant underlying illness such as systemic lupus erythematosus¹¹⁸ or transplantation and less frequently or never in patients who are not chronically ill but are on steroids for an acute event such as head injury. Recent observations that corticosteroids induce osteonecrosis in SARS patients further support the notion that more than one insult to the bone or surrounding tissue may be necessary to precipitate osteonecrosis. For each of the known associations of osteonecrosis, different mechanisms may predominate such as lipid anomalies and apoptosis of osteoblasts in steroid-induced osteonecrosis, as well as elevated intraosseous pressures and coagulation abnormalities in dysbaric osteonecrosis, but additional factors may be necessary to precipitate osteonecrosis. The accumulated cell stress theory suggests that when the damaging effects of multiple events are added together, the involved bone is unable to recover from the chronic stress and osteonecrosis ensues.

Genetic Considerations

The degree to which genetics and the environment play in the pathogenesis of osteonecrosis is the subject of an ongoing investigation. Certainly, single nucleotide polymorphisms have been noted in a number of genes that may be associated with osteonecrosis. It has been argued that endothelial nitric oxide synthase is an important player in the development of osteonecrosis. Nitric oxide may have beneficial effects on three systems involved in osteonecrosis, namely skeletal, vascular, and thrombotic. Each of these may be targets for proposed mechanisms of pathogenesis of osteonecrosis. A comparative analysis of the 26-base pair repeat polymorphism in intron 4 and the Glu298Asp polymorphism in exon 7 of the eNOS gene in patients with idiopathic, steroid-induced, alcohol-induced, and normal control subjects was performed.¹¹⁹ The frequency of the homozygous 4a allele was found to be higher in patients with idiopathic osteonecrosis compared with control subjects. The frequency of the 4a/b allele was found to be higher in all types of osteonecrosis when compared with control subjects. The 4a allele is known to be associated with reduced synthesis of endothelial nitric oxide synthase, suggesting that nitric oxide may play a protective role against the development of osteonecrosis.

Forty-one percent of patients with osteonecrosis compared with only 20% of controls were homozygous for the 4G/4G mutation in the plasminogen activator inhibitor-1 gene.¹²⁰ This mutation causes increased hypofibrinolytic plasminogen activator inhibitor activity, resulting in decreased stimulated plasminogen activator activity. This observation lends support to the theory that procoagulants may play a significant role in the pathogenesis of osteonecrosis. A polymorphism in the plasminogen activator

inhibitor-1 (*PAI-1*) gene has also been reported to be predictive of osteonecrosis in children with acute lymphoblastic leukemia.¹²¹

Genetic variations in type and levels of lipoprotein (a) have been linked to osteonecrosis. Apo(a) is involved in lipid metabolism and the coagulation systems, and the Apo(a) low-molecular-weight phenotype is associated with an increased risk of osteonecrosis.¹²²⁻¹²⁴ Polymorphisms in the promoter for vascular endothelial growth factor (VEGF) and in the receptor for IL-23 were associated with osteonecrosis in the Korean population,^{125,126} reflecting the significance of the association of osteonecrosis with vascular disorders and autoimmune diseases, respectively.

DIAGNOSIS

History and Physical Examination

The diagnosis of osteonecrosis is generally made by history because many patients may not present until they develop hip pain. By the time the patient is clinically symptomatic, the disease may be quite advanced. Therefore a high index of suspicion is necessary for all patients on oral or parenteral steroids. Information that should be elicited from a good history should include any history of trauma; underlying disease; alcohol use; tobacco use; current medications; past medications; history of joint anomalies; presence of pain or limitation of motion; involvement in sports, especially

high-impact sports; occupational history; gestational history; and the presence of liver disease or lipid abnormalities.

A good physical examination includes palpating the hip for tenderness, identification of limp, masses, leg-length discrepancy, the presence of masses, abnormal gait, muscle strength, and range of motion.

The Harris hip score is frequently used for evaluation of hip function and is also useful in monitoring the effectiveness of treatment (Figure 103-2).¹²⁷⁻¹²⁹ The Harris hip score is a multidimensional observational assessment based on eight items that address pain, walking function, daily activity, and range of motion. Scores range from 0 (maximum disability) to 100 (no disability).

Radiologic Imaging

When the diagnosis is suspected clinically, it can be confirmed by radiologic imaging studies. Earlier employed imaging techniques such as conventional radiography were inadequate in establishing the diagnosis because in the early stages of osteonecrosis radiographs may be completely normal. The earliest radiographic sign of osteonecrosis is the presence of a radiolucent crescent-shaped rim along the contour of the femoral head (crescent sign) (Figure 103-3). This appearance on radiographs is the result of structural collapse of a necrotic segment of subchondral trabecular bone. At this stage, the disease is already irreversible. Later, radiographs will begin to show sclerotic changes

Hip joint evaluation system

Figure 103-2 Harris hip score.

Figure 103-3 A radiolucent crescent in the subchondral region of the left femoral head (arrow) is an early radiographic sign of osteonecrosis.

(Figure 103-4). The appearance of radiographic “density” is secondary to compression of bone trabeculae after microfracture of the nonviable bone, calcification of detritic marrow, and repair of the necrotic area by deposition of new bone, the so-called *creeping substitution*. Flattening of the articular surface of bone is the sign of further bone collapse (Figure 103-5). To show best the radiographic appearance of osteonecrosis in the femoral head and better visualize the extent of the necrotic lesion, anteroposterior and frog-leg lateral films of the hip should be obtained.

Skeletal scintigraphy (radionuclide bone scan) using technetium-labeled diphosphonates has also been used to diagnose osteonecrosis. The use of this technique in the

early diagnosis of this condition depends on the fact that osteoblastic activity and blood flow are increased in the early stages of osteonecrosis. In an advanced stage of disease, the appearance may be one of increased activity in a subchondral distribution owing to osteoblastic activity at the reactive interface around the necrotic segment; however, the center of the osteonecrotic lesion may show much less radionuclide uptake (Figure 103-6) or even a complete lack of activity, reflecting decreased metabolism in the necrotic focus as a result of interruption of blood supply.⁶

In addition to bone scintigraphy, single-photon emission computed tomography (SPECT) maximizes sensitivity. A study comparing conventional radiography, MRI, computed tomography (CT), and Tc99m MDP three-phase bone scan in diagnosing bisphosphonate-associated osteonecrosis of the jaw showed that CT and MRI were the best at defining the extent of the disease, but that bone scan was the best at identifying disease at an early stage. Bone scan could be an excellent screening tool for the diagnosis of osteonecrosis before further characterization of the lesions using CT or MRI.¹³⁰

CT allows more detailed examination of the femoral head. A star-shaped structure, formed by weight-bearing bone trabeculae, gives the appearance of an asterisk on CT scan (the asterisk sign).¹³¹⁻¹³³ This asterisk undergoes a characteristic change in ischemic bone necrosis of the femoral head, and this change was considered important for early detection of osteonecrosis. At a later stage, the collapse of necrotic bone can be well shown (Figure 103-7).

Currently, MRI is the “gold standard” for imaging of osteonecrosis. Most of the staging systems for osteonecrosis are now based on MRI appearance (Table 103-6). MRI of osteonecrosis can show changes earlier than conventional radiography or CT. It can also detect bone marrow edema,

Figure 103-4 Anteroposterior (A) and frog-leg (B) views of the left hip showing sclerotic changes of the femoral head typical of advanced osteonecrosis.

Figure 103-5 Increased density of the femoral head, loss of the normal spherical shape, and flattening of the superior aspect are characteristic radiographic features of osteonecrosis.

a feature sometimes seen in the early phases of osteonecrosis that is not visible on conventional radiography or CT.

The typical MRI findings in osteonecrosis are intermediate or low signal intensity on T1-weighted images and high signal intensity on T2-weighted images (Figure 103-8). As the disease progresses, the subchondral necrotic lesion is surrounded by a low signal line on T1-weighted images. A high signal line is seen on T2-weighted images, central to the low signal line. This produces the “double-line” sign (Figure 103-9). In advanced osteonecrosis, the necrotic segment exhibits low signal intensity on both T1-weighted

Figure 103-6 Bone scintigraphy of osteonecrosis of both femoral heads using Tc99m methylene diphosphonate showing moderate uptake of radiopharmaceutical at the site of the osteonecrotic segment in the right femoral head and markedly increased uptake at the site of bone repair (straight arrow). The left femoral head (curved arrow) exhibits early-stage disease.

Figure 103-7 **A**, Computed tomography scan shows osteonecrosis of the femoral head. Although there are several sclerotic foci within the trabecular bone, the integrity of the osseous structures is preserved and the femoral head exhibits normal spherical shape. **B**, In more advanced stage of osteonecrosis of the femoral head, note increased sclerosis in the posterior aspect (solid arrow) and subchondral collapse of necrotic bone anterolaterally (open arrow).

and T2-weighted images (Figure 103-10). MRI is done in the sagittal, coronal, and axial planes and includes T1-weighted and T2-weighted sequences. There is excellent correlation between histologic findings and MRI appearance (see Table 103-6).

MRI is an important tool in determining the extent of femoral head involvement in osteonecrosis. Three techniques are used to evaluate this. The first is estimating head involvement. This method was first proposed by Steinberg and colleagues¹³⁴ in 1984, and it is defined by the appearance of abnormal signals on T1-weighted images. The degree of head involvement was classified into three categories: less than 15%, 15% to 30%, and greater than 30%. The second method used to evaluate extent is the index of

Table 103-6 Magnetic Resonance Imaging (MRI) Changes and Their Correlation with Histology in Osteonecrosis

Type of Appearance	Category of Observations	Histology	MRI Appearance
A	Fatlike	Premature fatty marrow development in the femoral neck or intertrochanteric region	Normal fat signal; Sclerotic margin may be seen circumscribing lesion
B	Bloodlike	Bone resorption; replacement by vascular granulation tissue	High signal intensity of inner border; low signal intensity of surrounding rim
C	Fluid-like	Bone marrow edema	Diffusely decreased signal on T1-weighted images; high signal on T2-weighted images
D	Fibrotic	Sclerosis owing to reinforcement of existing trabeculae at margin of live bone (repair tissue interface)	Decreased signal on T1-weighted and T2-weighted images

necrotic extent, which is determined by measuring the angle created by the extent of subchondral involvement. Lesion size was estimated using a “necrotic arc angle,” defined by the angle of the arc of the necrotic segment from the center of the femoral head. Two angles are obtained: “A,” representing the necrotic arc seen on midcoronal images, and “B,” representing the necrotic arc angle seen on midsagittal images. The index is a compilation of these two angles. The third method is a variation of the second, in which the angle is identified not on midcoronal or midsagittal images but on the image that shows the maximum lesion size in the sagittal and coronal planes. It is thought that this method would correct for the underestimation that may be inherent in the second method.

Table 103-7 shows a comparison of various imaging techniques used in the diagnosis and staging of osteonecrosis. Hip arthroscopy is also used in the staging of osteonecrosis. In a study comparing radiography, MRI, and arthroscopy, there was only moderate correlation among the three methods. Arthroscopy was able to detect osteochondral degeneration, not detected by radiography or MRI in 36% of collapsed heads. Figure 103-11 is an algorithm for the diagnosis of osteonecrosis.

Markers of Disease

The ability to find consistent and reliable markers of disease is always a welcome tool, for diagnosis, determination of extent of the disease, or even determination of risk of acquiring the disease. The measurement of serum and urine carboxy-terminal cross-linking telopeptide of type I collagen (CTX-1), a marker of bone resorption, has been proposed as a method of evaluating the risk of osteonecrosis of the jaw secondary to bisphosphonate usage. Serum osteocalcin is another marker for bisphosphonate-related osteonecrosis of the jaw that has been suggested as a risk predictor because levels were significantly lower in the osteonecrosis group compared with a control group.¹³⁵

TREATMENT

Surgical Treatment

Most cases of osteonecrosis ultimately require surgical intervention. There are various surgical techniques ranging from core decompression to total hip replacement. Sometimes surgical procedures can be used in conjunction with

Figure 103-8 **A**, On T1-weighted coronal magnetic resonance image of the left hip, the osteonecrotic segment in the subchondral portion of the femoral head shows low signal intensity. **B**, On T2-weighted coronal image, the necrotic bone exhibits high signal intensity, surrounded by a sclerotic low-signal rim.

Figure 103-9 Coronal T2-weighted magnetic resonance image of the right femoral head shows the double-line sign, characteristic for osteonecrosis: low signal at periphery of the lesion and high signal band located more centrally.

nonsurgical approaches, as discussed later. The more advanced the disease, the more extensive the surgery.

The various surgical procedures used in the treatment of osteonecrosis include core decompression, structural bone grafting, vascularized fibula grafting, osteotomy, resurfacing arthroplasty, hemiarthroplasty, and total hip replacement. Table 103-8 shows the typical success rates for each of these procedures.

Arthroscopy is a valuable tool used in the treatment of osteonecrosis. It has been used to determine the position of the core decompression tract to the necrotic part of the femoral head, and arthroscopic débridement has been used in the treatment of osteonecrosis of the capitellum of the

humerus in adolescents, Kienböck's disease, and osteonecrosis of the scaphoid.

Core decompression, which involves the removal of a core of bone from the femoral neck and head, is indicated in less advanced stages of osteonecrosis. The core acts as a vent to reduce intraosseous pressure and intramedullary pressure, reversing ischemia and improving symptoms. Other benefits of core decompression include stimulation of angiogenesis, which leads to improved vascularization during the repair process. The effectiveness of core decompression in the treatment of nontraumatic osteonecrosis was illustrated in 34 patients with 54 affected hips. Mean age at presentation was 38 years. The patients were monitored for a mean duration of 120 months postsurgery. Success was defined as absence of symptoms, no further progression of disease, and no further surgery. Clinical success was established in 26 hips (48%), and radiographic success was established in 20 hips (37%).

Computer-assisted core decompression has been used to provide greater precision in directing the core into the ischemic area and to minimize the duration of radiation exposure to patients.¹³⁶ Because early diagnosis improves outcome and there is a high incidence of developing osteonecrosis in a contralateral hip, core decompression is frequently done on both hips simultaneously. This approach adds little risk over unilateral core decompression with the benefit of better outcomes secondary to early surgical treatment of the contralateral hip.¹³⁷

In structural bone grafting, or bone impaction grafting, the bone graft is inserted into the necrotic segment through the core tract. The bone graft acts in similar fashion to a stent, providing support to overlying subchondral bone. The goal is to prevent collapse. This combination of procedures is frequently used in treating stage 1 or 2 osteonecrotic femoral heads. Allogeneic and autologous bone grafts, mostly harvested from the tibia or fibula, are used. When this technique was attempted in patients with stages 3 and 4 lesions, the outcome was generally poor (100% failure

Figure 103-10 Advanced osteonecrosis of the right femoral head exhibits low signal intensity on T1-weighted (A) and T2-weighted (B) MR images.

Table 103-7 Comparative Sensitivity and Specificity of Diagnostic Radiologic Imaging Modalities in Osteonecrosis

Radiologic Imaging	Earliest Sign Seen	Histologic Correlation	Stage	Degree of Specificity
Conventional radiograph	Crescent sign	Sclerotic rim of reactive bone	2	High
Computed tomography scan	Asterisk sign	Sclerotic rim surrounding a mottled area of osteolysis and sclerosis	2	High
Magnetic resonance image	Low signal intensity on T1-weighted images; high signal intensity on T2-weighted images	Bone marrow edema	1	High
Skeletal scintigraphy	Decreased uptake in subchondral distribution, "cold" spot	Osteonecrosis	1	Low
	Increased uptake in subchondral distribution, "hot spot"	"Creeping substitution"	2	Low

after 2 to 4 years), with progression to collapse and further surgical procedures.¹³⁸

Vascularized structural bone grafting also uses the core tract to insert a corticocancellous bone graft into the femoral neck and head along with its vascular pedicle. The vascular pedicle is anastomosed to a nearby vessel, adding a source of blood to the graft. The results of vascularized fibular grafting in the treatment of hips with osteonecrosis showed a

survival of 61% of hips at 5-year follow-up and 42% at a median time of 8 years.¹³⁹ In another study, 197 patients with 226 osteonecrotic hips were treated with a combination of autologous cancellous bone impaction and pedicled iliac bone block transfer. The anastomosis was to the ascending branch of the lateral femoral circumflex artery. Fourteen hips required conversion to total hip arthroplasty because of collapse, severe pain, or both. Of the remaining

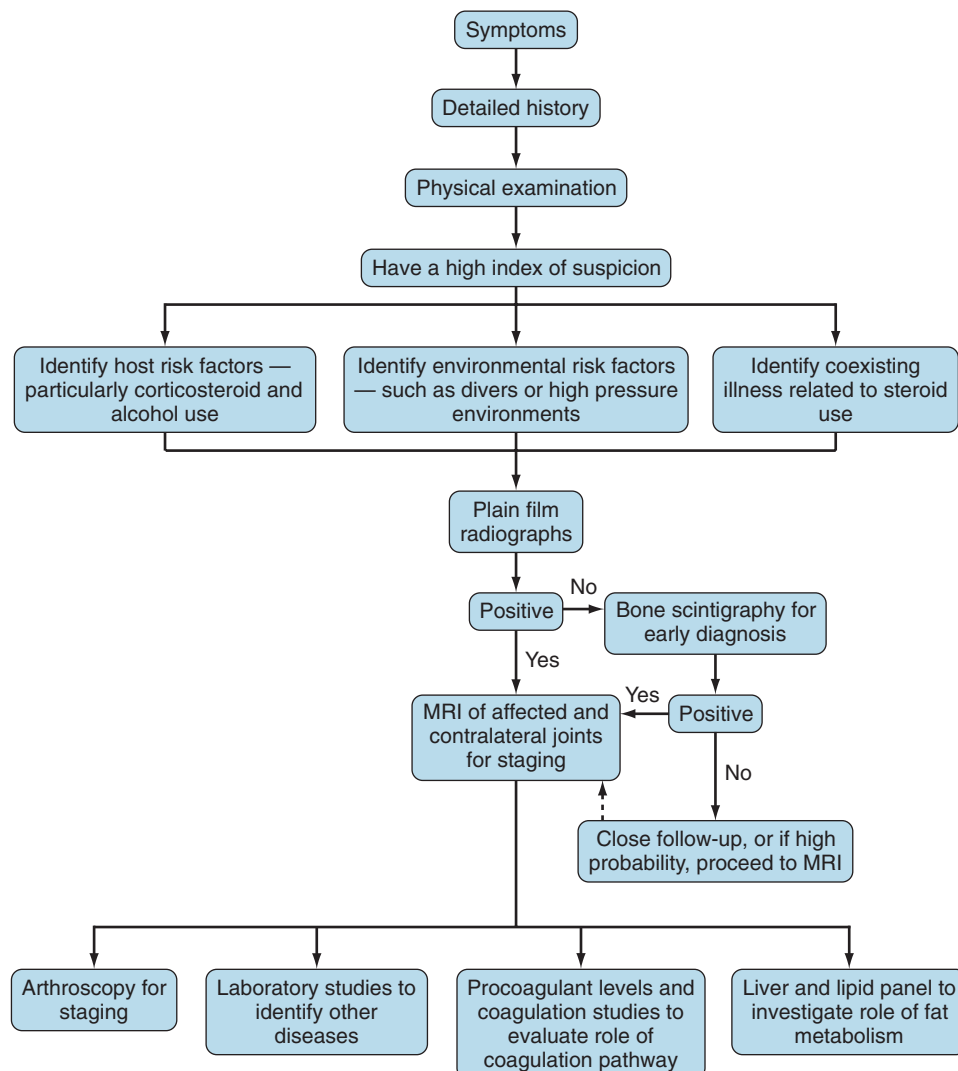

**Figure 103-11** Diagnostic algorithm for osteonecrosis. MRI, magnetic resonance image.

Table 103-8 Surgical Treatment of Osteonecrosis

Surgical Procedure	Rationale	Stages of Osteonecrosis	Outcome	Comments
Core decompression	Reduction of intraosseous and intramedullary pressure	Early stages	37% radiographic success, 48% clinical success	Success rate depends on disease stage
Structural bone grafting	Provide support to overlying subchondral bone	1 or 2	Poor in advanced disease	100% failure rate in stages 3 and 4
Vascularized fibula grafting	Increase blood flow to graft	2 to 4	96% success in stage 2, 90% in stage 3, and 57% in stage 4	
Osteotomy	Shifting position of osteonecrotic segment out of weight-bearing region	2 and 3	Not available	
Resurfacing arthroplasty	Preservation of bone and joint mechanics with metallic or ceramic shell over femoral head	Later stages	Mean 7-year success rate is 90%	An alternative to total hip arthroscopy in later stages of disease
Hemiarthroplasty	Replacement of femoral head, preservation of anatomic acetabulum	Later stages	Failure rate for unilateral hemiarthroplasties is 50%-60% at 3 years, for bilateral hemiarthroplasties is 44%	Various techniques available, some with better outcome
Total hip replacement	Complete replacement of the hip joint	Late stages	17.4% required revision after 10 years	Eventually most patients will require multiple hip replacements

212 hips, 92% were considered a clinical success and 76% were considered radiographically successful. The success rate declined from stage 2 to stage 4 hips (96% for stage 2 hips, 90% for stage 3 hips, and 57% for stage 4 hips).¹⁴⁰ Free vascularized fibula grafting has been compared favorably with other modes of surgical treatment.¹⁴¹

Osteotomy of the femur involves shifting the position of the osteonecrotic segment by making a cut in the proximal femur so that the osteonecrotic segment is rotated or flexed out of the weight-bearing region of the acetabulum and replacing the weight-bearing region with viable bone. Healing of the necrotic region can proceed without the stress of weight bearing. Several different osteotomy techniques have been attempted to salvage hips in stage 2 or 3 osteonecrosis.

Resurfacing arthroplasty uses a metallic or ceramic shell placed over a femoral head that has been débrided of the necrotic area. The potential advantages of resurfacing arthroplasty include preservation of joint mechanics, bone conservation,¹⁴² more physiologic loading of the bone, a lower incidence of perioperative complications, and easier conversion to total hip arthroplasty in case of failure.¹⁴³ Complications of this procedure include femoral neck fractures, a secondary osteonecrosis when the procedure is done for other reasons,¹⁴⁴ and increased metal ion levels.¹⁴⁵ Resurfacing arthroplasty has been recommended for patients with later-stage osteonecrosis including those with femoral head collapse.¹⁴⁶ A retrospective study compared the results of limited femoral head resurfacing and total hip arthroplasty in 30 consecutive patients with Steinberg stage 3 or 4 disease. The survival rate at a 7-year mean follow-up period for the resurfacing group was 90%, whereas the survival rate at a mean 8-year follow-up for the total hip arthroplasty group was 93%.¹⁴⁷ A recent level 3 therapeutic study showed that hip resurfacing success rates at a 5-year follow-up were comparable with those of total hip arthroplasty in osteonecrosis patients younger than 25 years of age.¹⁴⁸

In hemiarthroplasty, only part of the hip joint is replaced. The original acetabulum is preserved, but the femoral head is replaced with a prosthesis. Two kinds of prostheses are used—a unipolar prosthesis and a bipolar prosthesis. In a unipolar prosthesis, the articulation is between the artificial femoral head and the acetabulum. In the bipolar prosthesis, presently the most frequently used, the articulation is within the prosthesis itself. Failure rates for hemiarthroplasties in osteonecrosis are 50% to 60% at 3 years for unipolar prostheses and 44% for bipolar prostheses. Another study evaluated the success rate of Charnley/Bicentric hemiarthroplasty in the treatment of Ficat and Arlet stage 3 osteonecrosis of the femoral head. Failures include three hips that needed to be revised to cementless total hip replacement, two hips with radiographic changes of loosening and imminent failure, and one hip with progressive loss of joint space and secondary degenerative changes. The success rate was 84.2% after a mean of 56 months.

Total hip arthroplasty is complete replacement of the hip joint with a prosthesis including the femoral head and the acetabulum. In a study of 55 consecutive hip arthroplasty procedures, cementless total hip arthroplasty was shown to provide favorable results in advanced-stage osteonecrosis of the femoral head. Although 10 of the 48 hips available for follow-up after a minimum of 5 years required revision, all of these patients had Ficat and Arlet stage 3 or 4 disease. A study of 53 hips in 41 patients treated with cemented total hip replacement showed that at a minimum of 10 years of follow-up, 17.4% required revision. Compared with cemented total hip replacements done for other conditions, osteonecrosis had a greater risk for loosening of acetabular and femoral components. A survivorship analysis of cemented total hip replacements in renal transplant patients with osteonecrosis of the femoral head showed that there was excellent survival after 10 years (98.8%). After 20 years, the survival rate decreased to 63.8%.

In osteonecrosis of the jaw, the most common surgical procedure is resection of the affected bone.¹⁴⁹ Conservative

treatment has also been used but carries a higher recurrence rate. A larger extent of surgical excision and a higher number of surgical débridements were associated with a lower recurrence rate. Other modes of surgical therapy for osteonecrosis of the jaw include bone-contouring procedures; fluorescence-guided bone-contouring procedures¹⁵⁰; and segmental osteotomies, but these are generally reserved for more severe cases. Nonsurgical treatment including hyperbaric oxygen therapy¹⁵¹ and low-intensity laser therapy are controversial but have been used to treat osteonecrosis of the jaw.

Nonsurgical Approaches

The key to the successful treatment of osteonecrosis is early detection. The choice of conservative nonsurgical versus more aggressive surgical options depends on the clinical and pathologic staging of the disease. Figure 103-12 is an algorithm for the treatment of osteonecrosis.

Nonsurgical treatment of osteonecrosis of the femoral head includes refraining from weight bearing on the affected joint, analgesic and anti-inflammatory medications, and physiotherapy. Conservative medical treatment is effective only in the early stages for symptomatic relief. Nonsurgical

management does not seem to alter the natural course of the disease. Electrical stimulation has been used in the treatment of osteonecrosis, in conjunction with core decompression. Electrical stimulation enhances osteogenesis and neovascularization. It also alters the balance between osteoblast and osteoclast activity, resulting in increased bone deposition and decreased bone resorption. Delivery of electrical stimulation can be done by direct current (DC), pulsed electromagnetic field, and capacitance coupling. The success of electrical stimulation in the treatment of osteonecrosis has been rather mediocre. Eleven hips in eight patients with Ficat stage 2 osteonecrosis who underwent core decompression and placement of an electric stimulating coil within the core in the anterosuperior segment of the femoral head were studied. Of these, five hips required reoperation and six hips had progressive deterioration 13 months after initial placement of the coil. In addition, there was little histologic evidence that the coil did indeed generate new bone deposition around itself.

On the other hand, a study compared the effectiveness of conservative nonsurgical treatment with core decompression with or without direct current electrical stimulation. The clinical symptom scores and the rate of progression to arthroplasty were best in the group with core decompression

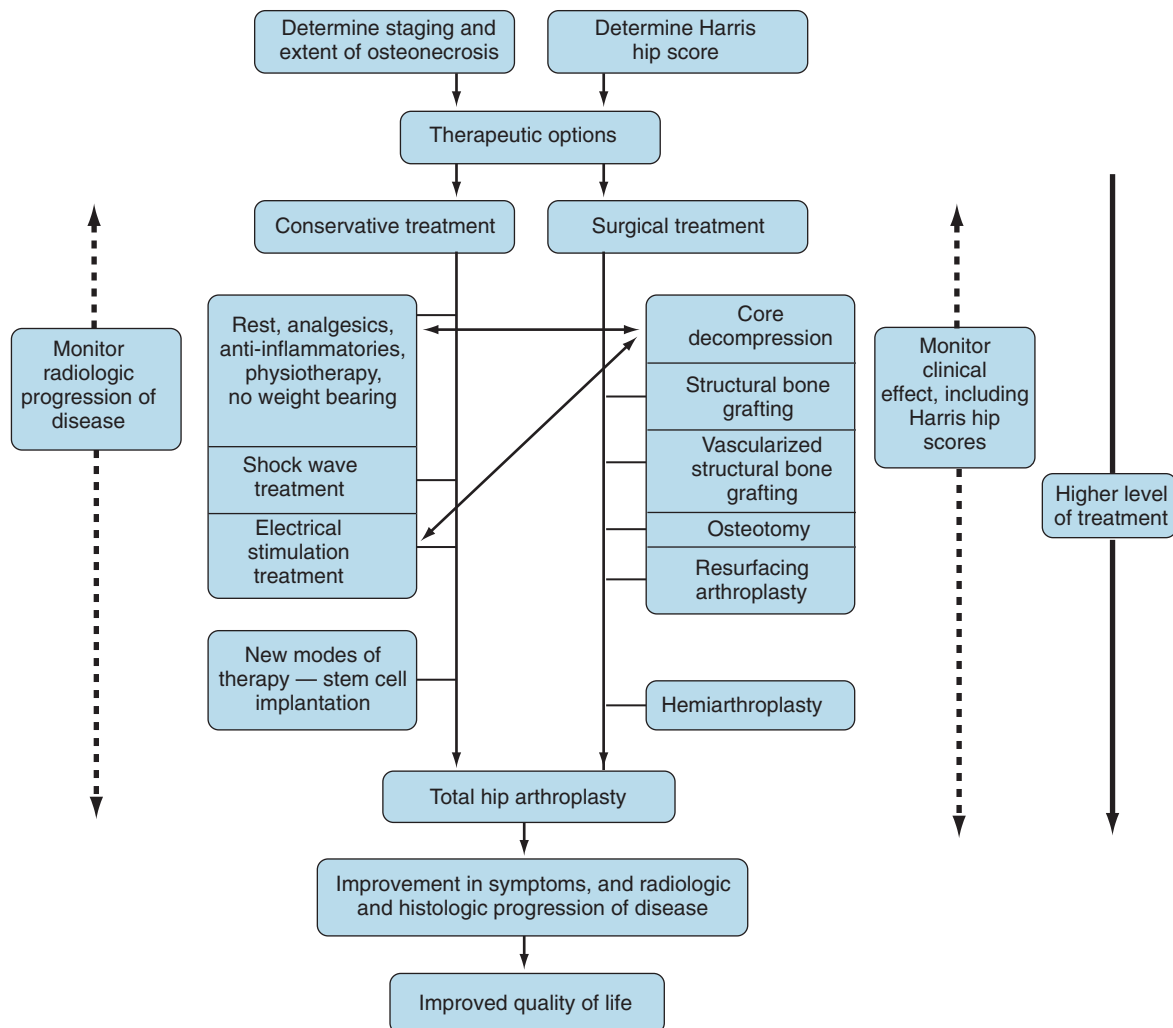

Figure 103-12 Treatment algorithm for osteonecrosis.

and DC electrical stimulation and worst in the nonoperative group. Capacitive coupling can be done with or without core decompression and grafting. Core decompression and grafting were done on 40 patients with stage 1 to 3 osteonecrosis; half of the patients wore active capacitive coupling units with electrodes over the femoral head for 6 months. The control group was 55 patients with osteonecrosis who were treated conservatively. Two- and 4-year follow-up showed that core decompression with or without capacitive coupling provided better clinical and radiologic outcome than conservative treatment. Capacitive coupling did not improve the results further when used with core decompression and grafting.

Extracorporeal shock wave therapy has been used in the treatment of osteonecrosis of the femoral head. A study of 48 patients and 57 hips compared extracorporeal shock wave therapy with core decompression and bone grafting. Twenty-three patients with 29 affected hips were assigned to the shock wave group, and the remaining patients and hips received surgical treatment. The patients in the shock wave group were given treatment of 6000 pulses of shock waves at 28 kV to the affected hip. The patients were evaluated radiographically and by their reports of symptoms (pain), Harris hip scores, and quality of life (daily work activity assessment). Shock wave therapy produced better results than the nonvascularized bone grafting procedure, with comparatively less progression of disease. In 35 patients with 47 osteonecrotic hips, the use of shock wave therapy led to improvements in serum nitric oxide levels, angiogenic factors such as VEGF, and osteogenic factors such as bone morphogenetic protein-2 (BMP-2) and osteocalcin. Levels of inflammatory markers were reduced. It is interesting to note that although these changes did not persist beyond several months, the clinical and radiographic improvement, present in 83% of hips, was present after 12 months.¹⁵²

Conservative treatment of osteonecrosis of the talus is not promising, and the affected ankles generally continue to progress, requiring either core decompression or arthrodesis. Conservative treatment of bisphosphonate-induced osteonecrosis of the jaw includes cessation of bisphosphonate usage or surgical débridement. Good oral hygiene, regular dental assessment, and avoidance of dental procedures during bisphosphonate usage can prevent onset of osteonecrosis.

RECENT DEVELOPMENTS

Prevention versus Treatment

A recent study evaluated the role of antioxidants in the treatment of osteonecrosis. Japanese white rabbits were divided into two groups and fed either a normal diet or a normal diet supplemented with α -tocopherol. Osteonecrosis developed in 14 of 20 rabbits in the control group but only in 5 of 21 rabbits in the experimental group. This suggests that oxidative stress may play a role in the pathogenesis of osteonecrosis and that there may potentially be a role for antioxidants such as vitamin E.¹⁵³

A group of researchers studied the use of adrenocorticotrophic hormone (ACTH) in rabbits to prevent corticosteroid-induced osteonecrosis and found that if

ACTH is administered along with depot methylprednisolone acetate (DepoMedrol), osteonecrosis is reduced. The authors of this study believe that ACTH enhances osteoblast support and stimulates the production of vascular endothelial growth factor (VEGF), which stimulates the generation of new blood vessels. The result is an increase in blood flow to the vulnerable areas of bone, preventing cell death and reducing the likelihood of osteonecrosis.¹⁵⁴

Mesenchymal Stem Cells

Corticosteroids interfere with the balance of adipogenesis and osteogenesis in the differentiation of mesenchymal stem cells. Corticosteroids shunt uncommitted osteoprogenitor cells in the bone marrow into the adipocytic pathway, leading to reduced osteoblast formation. Corticosteroids have also been shown to reduce vascular endothelial growth factor, which leads to a reduction in new blood vessel formation and potentially can lead to bone death. Alcohol has a similar effect on the differentiation of progenitor cells.

The balance between adipogenesis and osteogenesis has been targeted as a potential site for the treatment of osteonecrosis. Multipotential mesenchymal stem cells from femoral bone marrow near osteonecrosis sites are able to express messenger RNA aggrecan and type II collagen. Both are deposited into the bone matrix. These features are characteristic of chondrogenic differentiation. The mesenchymal stem cells can be differentiated into osteocytic lineage *in vitro*.

A pilot study evaluating the effectiveness of implantation of autologous bone marrow cells in the treatment of osteonecrosis used core decompression to implant stem cells into the necrotic lesions of the femoral head. The patients were divided into two groups—one that received core decompression alone as treatment for osteonecrosis (the control group) and one that received autologous bone marrow cell implantation along with core decompression (the treatment group). The patients were followed for 24 months, and at that time, 5 of 8 hips in the control group, but only 1 of 10 in the treatment group, advanced to stage 3 osteonecrosis. In addition, there was greater improvement in pain and joint symptoms in the treatment group and the treatment seemed to be safe. Because of the small number of patients involved, further studies are necessary to confirm these results.

Twenty-eight patients with 44 necrotic hips were treated with percutaneous decompression and autologous bone marrow mononuclear cell infusion. Patients were followed for a minimum of 2 years and evaluated for clinical and radiographic progression of the disease. There seemed to be overall slowing in the progression of the disease stage. The mean Harris hip score improved from 58 to 86.

OUTCOME

The natural history of osteonecrosis depends on the size of the infarcted segment, the site of occurrence, and the clinical and radiologic staging of the disease. At the onset of the disease, range of motion may be well preserved but gradually deteriorates over time. In the early stages of the disease, when it is still reversible, patients may be asymptomatic.

Many patients therefore present with advanced disease. Although spontaneous resolution of femoral head osteonecrosis can occur, it is rare and occurs only when lesion size is small. A study of the prognosis of osteonecrosis of the femoral head as a function of symptoms (pain) and radiographic findings showed that in patients who were asymptomatic and had normal radiographs, progression of the disease was slow, with only 1 of 23 hips progressing to pain and radiographic changes after 5 years. If radiographic changes are already present, disease progresses to pain in 14 of 19 patients after 5 years. In a study of stage 1 osteonecrotic lesions of the hip diagnosed with MRI, 40 patients were followed for an average of 11 years. All patients had stage 1 lesions on the contralateral hip. Overall, 35 of the 40 stage 1 hips became symptomatic and 29 hips showed collapse. The mean interval between diagnosis and collapse was 92 months, whereas the mean interval between symptoms and diagnosis was 80 months. Most stage 1 hips eventually progress to a more advanced stage, requiring surgery, so these hips should be monitored closely.

SUMMARY

Osteonecrosis is a potentially debilitating condition with significant morbidity despite medical interventions or surgery. Corticosteroids are the most common cause of osteonecrosis, and corticosteroid-induced osteonecrosis can be reproduced in animal models. The pathogenesis of osteonecrosis is multifaceted and still not completely understood. Why is it that corticosteroid-induced osteonecrosis is more common in patients with certain underlying diseases and not in others? Is there a genetic basis for osteonecrosis? Common pathogenic mechanisms known to be involved in osteonecrosis include osteoblast/osteoclast survival and apoptosis, lipid metabolism, and coagulation abnormalities. However, it is still unclear how these mechanisms interrelate with each other. In order to better appreciate the risk factors involved in osteonecrosis, a more complete understanding of the pathogenesis is necessary. Until then, the physician should always maintain a high index of suspicion for osteonecrosis whenever known risk factors are present, especially use of corticosteroids and alcohol.

Relapsing Polychondritis ■

GAYE CUNNANE

KEY POINTS

Relapsing polychondritis is a rare disorder that classically affects the cartilaginous structures of the ears and nose, resulting in “cauliflower ear” and “saddle nose” deformities.

It may cause significant pathology of the upper airways, eyes, inner ears, kidneys, and blood vessels with potentially life-threatening consequences.

It may develop in association with other diseases such as myelodysplasia, vasculitis, or other autoimmune/connective tissue disorders.

Due to the multisystem nature of the disease, a broad approach to diagnosis and management is essential.

Treatment is frequently empiric due to the wide variety of disease manifestations and lack of controlled trials. However, immunosuppression is the mainstay of therapy.

Relapsing polychondritis (RPC) is a rare autoimmune disease of unknown etiology, characterized by episodic inflammation of cartilaginous structures throughout the body (e.g., the ears, nose, upper respiratory tract, chest wall, joints). Associated diseases such as vasculitis or myelodysplastic syndromes occur in up to one-third of cases. The severity of the inflammatory process frequently requires the use of immunosuppressive agents. Prognosis is variable with a 5-year survival rate of 45% to 95% depending on organ involvement and disease or treatment complications.

EPIDEMIOLOGY

The worldwide incidence of RPC is unknown, but figures from Rochester, Minnesota, suggest an annual incidence of 3.5 per million in that community.¹ RPC occurs in all racial groups and with similar frequency in men and women. Peak age of onset is 40 to 50 years, but it has been described in children and in people older than 80 years of age. No familial pattern of inheritance has been shown.

PATHOLOGY

Cartilage has a cellular component consisting of chondrocytes and an extracellular matrix made from interlinking fibrils of type II collagen, other collagens, hydrophilic proteoglycan aggregates, and a variety of matrix proteins.² One such protein, matrilin-1, is exclusive to the respiratory tract, ears, and xiphisternum in adults and is only found in articular cartilage before skeletal maturity.³ Cartilage is an avascular structure that derives essential nutrients from adjacent tissue. The composition of cartilage confers

resilience to external compressive forces. In normal adults, turnover of cartilage components is slow, with incomplete repair processes.⁴ Degradation of collagen fibrils occurs with age resulting from imbalances between naturally occurring proteolytic enzymes and their inhibitors.⁵

In RPC, typical features on hematoxylin-eosin staining include a loss of normal cartilage basophilia and a perichondrial inflammatory infiltrate composed of lymphocytes, neutrophils, eosinophils, and plasma cells.^{3,6} Necrosis and a reduction in cartilage components may be observed. The cartilage is subsequently replaced by fibrotic tissue.⁶ Immunofluorescence may demonstrate immunoglobulin and complement components in the perichondrial tissue and vessels.⁷

PATHOGENESIS

Although the pathogenesis of RPC is unknown, evidence supports the concept of an autoimmune process. Researchers have observed autoantibodies to types II, IX, and XI collagen in patients with this disease,^{3,8-10} while autoantibodies to matrilin-1 have been detected in those with respiratory tract involvement.¹¹ Specific cytokines such as monocyte chemoattractant protein-1, macrophage inflammatory protein 1 β , and interleukin-8 are significantly elevated in active RPC compared with controls.¹² Furthermore, there is a human leukocyte antigen (HLA) class II association with RPC. A twofold increase in HLA-DR4 has been found in RPC, although a specific subtype has not been identified.¹³

Several animal models have helped elucidate some of the pathogenetic mechanisms underlying RPC. Chondritis can be induced in certain rat or mice species following injection of type II collagen.^{14,15} In addition, mice expressing HLA-DQ6ab8ab transgenes develop a spontaneous form of polychondritis with auricular, nasal, and joint involvement.¹⁶ Experiments using the matrilin-1-induced rodent model of RPC have demonstrated the importance of T cells, B cells, and complement components in pathogenesis of this disease.¹⁷ Deletion of interleukin (IL)-10 in this model resulted in increased disease severity, suggesting a role for this endogenous cytokine in suppressing episodic inflammation.¹⁸

The processes involved in the initiation of disease, escalation of the inflammatory response, and subsequent cartilage destruction are poorly understood. In a healthy individual, cartilage is an immunologically privileged site. However, in RPC, cartilage components are exposed and vulnerable to immunologic attack, resulting in a perpetuating process of systemic inflammation and local tissue damage. In genetically susceptible individuals, cartilage

Table 104-1 Diagnostic Criteria

Major Criteria
Proven inflammatory episodes of ear cartilage
Proven inflammatory episodes of nose cartilage
Proven inflammatory episodes of laryngotracheal cartilage
Minor Criteria
Eye inflammation
Hearing loss
Vestibular dysfunction
Seronegative inflammatory arthritis
Diagnosis is made by two major criteria or one major plus two minor criteria.
Histologic examination of affected cartilage is not required.

From Michet CJ Jr, McKenna CH, Luthra HS, et al: Relapsing polychondritis: survival and predictive role of early disease manifestations, *Ann Intern Med* 104:74–78, 1986.

microtrauma or molecular mimicry between an infectious/inciting agent and cartilage structures might instigate a cycle of inflammation similar to other autoimmune disorders.

CLINICAL FEATURES

The diagnostic criteria for RPC are outlined in Table 104-1. Table 104-2 documents the frequency of clinical presentations.

Otorhinologic Disease

The most characteristic manifestation of RPC is auricular chondritis, in which the patient develops acute pain, redness, and swelling of the cartilaginous upper two-thirds of the outer ear, sparing the lobe¹⁹ (Supplemental Figure 104-1 on www.expertconsult.com). It may be unilateral or bilateral and resolves spontaneously over a period of several weeks. Repeated episodes result in visible damage to the ear, with a deformed, flaccid appearance (Figures 104-1A and 104-2). Although classic in RPC, it is the presenting feature in only 40%, whereas up to 85% of patients eventually develop this feature over the course of their disease.²⁰ Such swelling of the outer ear causes temporary conductive

Table 104-2 Clinical Features of Relapsing Polychondritis

Clinical Feature	Frequency	
	At Presentation	In Total
Auricular chondritis	39	85
Nasal chondritis	24	54
Arthritis	36	52
Eye disease	19	51
Laryngotracheal bronchial disease	26	48
Hearing loss	9	30
Rash	7	28
Systemic vasculitis	3	10
Valvular dysfunction	0	6
Costochondritis	2	2

Modified from Michet CJ, McKenna CH, Luthra HS, et al: Relapsing polychondritis: survival and predictive role of early disease manifestations, *Ann Intern Med* 104:74–78, 1986; and Gergely P, Poór G: Relapsing polychondritis, *Best Pract Res Clin Rheumatol* 18:723–738, 2004.

deafness. However, sensory-neural deafness may result from an associated vasculitis of the internal auditory artery or its branches, leading to additional vertigo in some patients.^{6,19}

A similar pattern of chondritis in the nose may cause collapse of the nasal bridge and an alteration of the facial appearance—the so-called saddle-nose deformity (Figure 104-1B).

Respiratory Disease

Involvement of the upper respiratory tract may be life threatening and should be investigated at an early stage in the disease course. Approximately 50% of patients with RPC develop respiratory problems, which are associated with a worse prognosis.²¹ Hoarseness, dysphonia, a persistent dry cough, or anterior neck tenderness may indicate laryngeal or tracheal disease. Inflammation of the tracheo-bronchial tree may lead to tracheomalacia, dynamic obstruction, and acute respiratory failure, whereas repeated inflammatory episodes cause subglottic stenosis, chronic dyspnea, and increased susceptibility to infection.²² Obstruction may be precipitated by attempts at intubation or bronchoscopy.⁶ Computed tomography and bronchoscopy appearances of one patient with RPC are demonstrated in Figure 104-1C and D. The development of costochondritis may result in chest pain, leading to additional respiratory symptomatology.

Cardiovascular Disease

Large and small vessel disease can occur during the course of RPC in up to 10% of cases.²³ Inflammation of the aorta, most likely to occur at the level of the root or arch, leads to aneurysm formation and aortic incompetence, which may develop acutely with minimal prior symptoms.^{6,24} Aortic valve disease may be due to progressive dilatation of the aortic ring rather than to active local inflammation.⁶ Mitral regurgitation may result from valvitis or papillary muscle involvement, whereas myocarditis may lead to cardiac failure and conduction system abnormalities.^{1,22,23} Small vessel vasculitis has also been reported and may cause end-organ damage to the skin, kidneys, testes, sclera, cochleovestibular system, or other areas.^{6,25} Arterial and venous thromboses have been described in association with RPC.⁶

Eye Disease

Approximately 50% of patients with RPC will develop ocular disease, most commonly episcleritis and scleritis. Uveitis, retinal vasculitis, and optic neuritis are rare complications. Keratoconjunctivitis sicca may occur with associated Sjögren's syndrome. Extraocular muscle palsy, periorbital edema, and proptosis may also occur as part of the RPC symptom complex.²⁶

Renal Disease

Proteinuria and/or hematuria may be observed on urinalysis in up to 26% of patients with RPC. Renal pathology has been reported to show mesangial proliferation and segmental necrotizing crescentic glomerulonephritis.²⁷

Supplemental Figure 104-1 A-F, This series of photographs depicts the ear of a 56-year-old man with relapsing polychondritis. His disease was uncontrolled for 1 year during which the damage shown developed in the cartilaginous structures of the ear.

Figure 104-1 **A**, Chronic changes of relapsing polychondritis (RPC) in the cartilaginous upper two-thirds of the ear, evident after repeated episodes of inflammation in this area. **B**, Saddle nose deformity, developed after episodic nasal chondritis. **C**, Bronchoscopy findings demonstrating mucosal hyperemia, edema with lack of normal detail of tracheal cartilaginous rings, and flattening of the trachea. **D**, Computed tomography thorax with arrow demonstrating tracheal flattening and calcification in a patient with RPC. (**A** and **B**, Courtesy Mr. Anthony Edwards, clinical photographer, St. James's Hospital, Dublin 8. **C** and **D**, Courtesy Dr. Finbarr O'Connell, consultant pulmonologist, St. James's Hospital, Dublin 8.)

Electron microscopy may demonstrate immunoglobulin and complement deposits. Renal pathology may also occur in the context of coexisting diseases such as systemic lupus erythematosus or other rheumatic diseases.

Neurologic Disease

Central and peripheral nervous system involvement is rare, affecting less than 5% of patients.²⁸ Cranial neuropathy is the most common manifestation, but a wide variety of problems including headache, ataxia, hemiplegia, transverse myelitis, mononeuritis multiplex, aseptic meningitis, and encephalopathy have been described. Such lesions may be vasculitic or autoimmune in nature.^{1,29}

Skin Disease

Dermatologic manifestations develop in approximately 35% of patients with RPC, relating to the underlying disease or an associated syndrome.^{1,30} Skin changes are more likely to occur in patients with concurrent RPC and myelodysplasia.³⁰ Oral aphthous ulcers are the most common symptom. Peripheral nodules, similar to erythema nodosum, exist in approximately 15% of patients.³⁰ Rare skin lesions include

peripheral limb ulcers, livedo reticularis, panniculitis, superficial thrombophlebitis, urticaria, and angioedema. Leukocytoclastic vasculitis, dermal vessel thrombosis, or septal panniculitis may manifest on biopsy.³⁰

Joint Disease

Musculoskeletal manifestations are common and develop in 75% over the course of the disease.^{1,23} Involvement of the joints may be oligoarticular or polyarticular, most commonly affecting the ankles, wrists, hands, and feet. However, other joints, including the sacroiliac joints, may also show evidence of disease, although it is possible that the presence of sacroiliitis relates to the coexistence of a spondyloarthropathy.³¹ The arthritis associated with RPC is typically episodic and nonerosive, and it does not correlate with activity of RPC.^{22,23}

ASSOCIATED DISORDERS

RPC has been described in association with a variety of other disorders including hematologic, rheumatic, and vasculitic syndromes. Its coexistence with Behçet's disease has led to the acronym **MAGIC syndrome**: mouth and genital

Figure 104-2 Chronic changes of relapsing polychondritis in the cartilaginous upper two-thirds of the ear, evident after repeated episodes of inflammation in this area.

ulcers with inflamed cartilage.³² In older patients, RPC may be associated with myelodysplasia and a worse prognosis^{33,34} (Table 104-3).

DIFFERENTIAL DIAGNOSIS

Auricular chondritis with sparing of the earlobe is characteristic of RPC. Redness and swelling of the whole ear including the earlobe may be the result of trauma or exposure to temperature extremes and should be distinguished

Table 104-3 Diseases Associated with Relapsing Polychondritis

Rheumatic Disorders
Rheumatoid arthritis
Seronegative spondyloarthropathies
Connective tissue disorders
Vasculitides
Hematologic Disorders
Myelodysplasia
Lymphomas
Pernicious anemia
Acute lymphoblastic leukemia
Endocrine Disorders
Type I diabetes mellitus
Thyroid disorders: Hashimoto's/Graves' disease/hypothyroidism
Other Disorders
Inflammatory bowel disease
Primary biliary cirrhosis
Retroperitoneal fibrosis
Myasthenia gravis

from RPC. *Pseudomonas aeruginosa* or *Staphylococcus aureus* are potential causes of unilateral otitis externa, particularly in immunocompromised patients.³⁵ Other infections associated with chondritis include leprosy and syphilis. Damage to the nose cartilage may be due to trauma, local infections, or granulomatous lesions such as antineutrophil cytoplasmic antibody (ANCA)-associated granulomatous vasculitis or lethal midline granuloma. Intranasal cocaine use should also be considered. A wide variety of inflammatory, rheumatic, and infectious conditions may mimic some features of RPC, particularly when multiple organs are involved. Cogan's syndrome is an inflammatory autoimmune condition that results in keratitis and vestibulo-auditory symptoms and may be associated with vascular inflammation, although it is not linked with chondritis.³⁶ Causes of systemic vasculitis (e.g., ANCA-associated vasculitis, polyarteritis nodosa, Behçet's syndrome, rheumatoid arthritis, or those associated with connective tissue disorders) should be taken into consideration, especially when the presentation is atypical. Valvular heart disease, particularly aortic incompetence and aortic root dilatation, may occur in conditions such as Marfan's syndrome, syphilis, and idiopathic medial cystic necrosis and can also develop in relation to diseases that may coincide with RPC (e.g., ankylosing spondylitis).

INVESTIGATIONS

Routine Laboratory Tests

Routine laboratory tests should be performed and may demonstrate nonspecific findings such as anemia or mild thrombocytosis. The acute phase response is typically elevated during periods of inflammation. Urinalysis should always be performed to determine the presence of subclinical renal disease or infection. Autoimmune tests are nonspecific, except where associated diseases are present concurrently.

Tissue Sampling/Histopathology

In typical presentations of RPC, a biopsy is not indicated for diagnosis. However, where the diagnosis is unclear, a biopsy of inflamed cartilage may show evidence of perichondritis, as described earlier.^{3,6} Skin rashes may demonstrate leukocytoclastic vasculitis; other frequent findings include panniculitis, neutrophilic dermatoses, or dermal vessel occlusion.³⁰

Pulmonary Investigations

Clinicians should conduct pulmonary function tests in all suspected cases of RPC and should be repeated in the event of new respiratory symptoms. If abnormal, computed tomography of the chest is recommended to detect the presence of tracheal or bronchial stenoses or dynamic airway collapse, which may be evident only during the expiratory phase of the respiratory cycle.³⁷ Extrapulmonary disease from costochondritis may cause a restrictive pattern on pulmonary function testing.

Bronchoscopy is warranted only if specifically indicated in order to avoid inadvertent damage to the upper airways, which poses the risk of precipitating respiratory failure. However, indirect laryngoscopy is helpful to monitor airway

involvement. Bronchoscopic ultrasound can also be used to monitor disease.³⁸

Cardiac Investigations

Echocardiography is necessary to evaluate the aortic root and heart valves.

Many systemic inflammatory diseases are associated with accelerated atherosclerosis, and this may also be true for patients with RPC, although due to small numbers of cases, this has not been widely described. Nevertheless, other cardiac disease risk factors should be ascertained.

Ocular Investigations

Routine retinoscopy should be performed at diagnosis. Referral to a specialist unit is recommended if abnormalities are detected and/or if symptoms develop.

Musculoskeletal Tests

Plain radiographs of involved joints may show joint space narrowing or periarticular osteopenia. Erosions are not observed, unless there is an associated rheumatic disorder. Dual x-ray absorptiometry may demonstrate osteopenia as a consequence of the underlying inflammation or general debility.

Additional Investigations

At present genetic testing offers little added benefit. Markers of cartilage autoimmunity such as antibodies to types II, IX, or XI collagen or matrilin-1 are not routinely available, and their role in disease activity monitoring is unclear. A recent report highlighted the relevance of antiglutamate receptor GluR $\epsilon 2$ autoantibodies in the cerebrospinal fluid and sera of a patient with limbic encephalitis.²⁹ The potential use of other biomarkers such as urinary type II collagen breakdown products has been demonstrated.³⁹ Additionally, a recent study showed that serum levels of cartilage oligomeric matrix protein (COMP) are elevated during disease flares in RPC.⁴⁰

TREATMENT

Nonsteroidal anti-inflammatory drugs and low-dose corticosteroids may successfully control minor inflammation of the nose, ear, or chest wall. Dapsone may also be used for non-critical cartilaginous inflammation,^{1,21} and colchicine is of reported use in auricular chondritis.⁴¹ However, the presence of potentially life-threatening disease or severe chondritis requires high-dose prednisone, typically at a dose of 1 mg/kg, reducing slowly as the inflammation recedes.^{1,23} Although the RPC is usually steroid responsive, it can be difficult to withdraw these drugs completely without risking a flare in disease activity and many patients require maintenance doses of prednisone and consideration of alternative immunosuppression. Disease-modifying treatment is indicated in patients who require a steroid-sparing agent and in whom serious manifestations such as vascular or respiratory disease have developed.

Due to the rarity of this disease, there are no controlled trials of therapeutic interventions in RPC. However, methotrexate, cyclophosphamide, mycophenolate mofetil, azathioprine, chlorambucil, and cyclosporine have had successful therapeutic outcomes in some patients.^{6,42–49} Varied outcomes have been reported with leflunomide.^{50,51} Plasmapheresis has been employed in recalcitrant cases.^{6,23} There are several case reports and small case series detailing the use of biologic agents in this disease. However, there have been both positive and negative reports in relation to the anti-tumor necrosis factor agents and anti-B cell drugs.^{24,52–57} Interleukin-1 receptor antagonist has demonstrated benefit in a small number of reported cases.^{58,59} Tocilizumab, an anti-IL-6 agent, has had beneficial effects in this disease.⁶⁰ A successful outcome for autologous stem cell transplantation in treatment-resistant RPC has also been reported.⁶¹ It is not clear, however, if any of these treatments overtly influence the natural history of this disease.

A broad approach to the management of RPC is essential. Awareness of disease complications and recognition of early pathology may be lifesaving. Special consideration should be given to the management of upper airway involvement, and the anesthesia team should be made aware of disease in this region before surgical intervention. Symptomatic airway obstruction might require tracheostomy, tracheal stenting, or nighttime positive pressure ventilation to prevent airway collapse while the patient is asleep. There is limited experience with laryngotracheal reconstruction in patients with this disease, and such interventions should only take place during disease quiescence.⁶² Heart surgery to treat aortic root dilatation, aneurysm formation, or valvular disease has a good outcome in most cases, although postoperative dehiscence is a complication in 12%.⁶³ Most cases require postoperative immunosuppression. For patients with sensorineural deafness, cochlear implantation is usually beneficial with significant restoration of hearing.⁶⁴ Neither hormonal activity nor pregnancy is thought to influence disease activity in RPC.⁶⁵ However, several case reports have described the treatment of disease flares during pregnancy, typically with corticosteroids, with successful maternal and fetal outcomes.^{65–67}

OUTCOME

RPC is an episodic, progressive disease that results in tissue destruction of target organs. Some patients have a mild course, complicated only by recurrent chondritis, whereas others develop potentially life-threatening problems. The most common cause of death is pulmonary infection, arising as a result of the disease or its immunosuppressive treatment.⁶ In young patients, adverse prognostic factors at presentation include anemia, hematuria, upper airway disease, arthritis, and saddle nose deformity, whereas in older patients (more than 51 years of age), only anemia at presentation predicts increased mortality.²⁰ The presence of vasculitis worsens prognosis, with a 5-year survival rate of 45%.²¹ In 1986 Michet and colleagues²⁰ reported the 10-year survival rate to be 55%, whereas in 1998, perhaps due to improvements in disease monitoring and treatment, Trentham and colleagues⁶ described a 94% survival rate.

Future Directions

An international database of RPC, detailing modes of presentation, clinical characteristics, and therapeutic responses, would be a valuable resource in learning more about the epidemiology and treatment of RPC. It would also help clarify some of the discrepancies in the current literature relating to presentation and prognosis of this rare disease. New therapies, with specific cellular or molecular targets, offer promise to patients with chronic inflammatory diseases but should ideally be accompanied by definitive knowledge of their mechanism of action in particular disease subtypes. Increased awareness of the immunogenic precipitants involved in RPC may help to guide future treatments and reduce morbidity and mortality in such patients.

KEY POINTS

Heritable disorders of connective tissues are a diverse group of disorders and can be associated with extreme variation in height ranging from very short (dwarfs) to tall stature.

The osteochondrodysplasias or skeletal dysplasias are a heterogeneous group of more than 450 disorders frequently associated with profound short stature and orthopedic complications.

These disorders are diagnosed on the basis of radiographic, morphologic, clinical, and molecular criteria.

The molecular mechanisms have been elucidated in many of these disorders providing for improved clinical diagnosis and reproductive choices for affected individuals and their families.

Mechanism-based treatment options that might improve the quality of life and life span in individuals affected with osteogenesis imperfecta and Marfan syndrome are being investigated. Newer advances in understanding the underpinnings of altered pathways in these disorders are providing potential new targets for treatment.

Heritable disorders of connective tissues are a heterogeneous group of disorders characterized by abnormalities in skeletal tissues including cartilage, bone, tendon, ligament, muscle, and skin. These disorders, originally defined by McKusick,¹ have been classified on the basis of clinical findings and molecular criteria. They are subclassified into disorders that primarily affect cartilage and bone (the skeletal dysplasias) and disorders that have a more profound effect on connective tissue including Ehlers-Danlos syndrome (EDS), Marfan syndrome, and other disorders manifested by abnormal extracellular matrix molecules. The skeletal dysplasias are associated with abnormalities in the size and shape of the appendicular and axial skeleton and frequently result in disproportionate short stature. Until the early 1960s, most individuals with short stature were considered to have pituitary dwarfism, achondroplasia (short-limb dwarfism), or Morquio disease (short-trunked dwarfism). Presently, there are more than 450 well-characterized disorders that are classified primarily on the basis of clinical, radiographic, and molecular criteria.² Disorders of connective tissue are genetic defects that result from mutations in genes that encode extracellular matrix proteins, transcription factors, tumor suppressors, signal transducers, enzymes, chaperones, intracellular binding proteins, ribonucleic acid (RNA) processing molecules, and genes of unknown function.

Heritable Diseases of Connective Tissue

DEBORAH KRAKOW

SKELETAL DYSPLASIAS

The skeletal dysplasias, or osteochondrodysplasias, are defined as disorders that are associated with a generalized abnormality in the skeleton. Although each skeletal dysplasia is relatively rare, collectively, the birth incidence of these disorders is almost 1 in 5000.³ These disorders range in severity from “precocious” arthropathy to perinatal lethality owing to pulmonary insufficiency. Individuals with these disorders can have significant orthopedic, neurologic, and psychological complications. Many of these individuals seek medical attention for orthopedic complaints owing to ongoing pain, arthritic complaints in large joints, and back pain primarily caused by ongoing abnormalities in bone and cartilage frequently leading to spinal stenosis.

Embryology

The human skeleton (from the Greek, *skeletos*, “dried up”) is a complex organ consisting of 206 bones (126 appendicular bones, 74 axial bones, and 6 ossicles). The skeleton including tendons, ligaments, and muscles in addition to cartilage and bone has multiple embryonic origins and serves many key functions throughout life such as linear growth, mechanical support for movement, a blood and mineral reservoir, and protection of vital organs.

The patterning and architecture of the skeleton occurs during fetal development (see Chapter 4). During that period, the number, size, and shape of the future skeletal elements are determined, a process that is under complex genetic control.⁴ Uncondensed mesenchyme undergoes cellular condensations (cartilage anlagen) at the sites of future bones, and this occurs via two mechanisms.⁵ In the process of endochondral ossification, mesenchyme first differentiates into a cartilage model (anlagen), and then the center of the anlagen degrades, mineralizes, and is removed by osteoclast-like cells. This process spreads up and down the bones and allows for vascular invasion and influx of osteoprogenitor cells. The periosteum in the midshaft region of the bone produces osteoblasts, which synthesize the cortex; this is known as the *primary ossification center*.

At the ends of the cartilage anlagen, a similar process leading to the removal of cartilage occurs (secondary center of ossification), leaving a portion of cartilage model “trapped” between the expanding primary and secondary ossification centers. This area is referred to as a *cartilage growth plate* or *epiphysis*. Four chondrocyte cell types exist in the growth plate: reserve, resting, proliferative, and hypertrophic. These growth plate chondrocytes undergo a tightly regulated program of proliferation, hypertrophy, degradation, and replacement by bone (primary spongiosa). This is the major mechanism of skeletogenesis and is the

mechanism by which bones increase in length, and the articular surfaces increase in diameter. In contrast, the flat bones of the cranial vault and part of the clavicles and pubis form by intramembranous ossification, whereby fibrous tissue, derived from mesenchymal cells, differentiates directly into osteoblasts, which directly lay down bone.⁵ These processes are under specific and direct genetic control, and abnormalities in the genes that encode these pathways frequently lead to skeletal dysplasias.⁶⁻⁹

Cartilage Structure

Collagen accounts for two-thirds of the adult weight of adult articular cartilage and provides significant strength and structure to the tissue (see Chapter 3). Collagens are a family of proteins that consist of single molecules (monomers) that combine into three polypeptide chains to form a triple helix structure. In the triple helix, every third amino acid is a glycine residue and the general chain structure is denoted as Gly-X-Y, where X and Y are commonly proline and hydroxyproline. The collagen helix can be composed of identical chains (homotrimeric), as in type II collagen, or can consist of different collagen chains (heterotrimeric), as seen in collagen type XI.¹⁰

Collagens are widely distributed throughout the body, and 33 collagen gene products are expressed in a tissue-specific manner, leading to 19 triple helical collagens. Collagens are classified further by the structures they form in the extracellular matrix. The most abundant collagens are the fibrillar types (I, II, III, V, and XI), and their extensive cross-linking provides mechanical strength that is necessary for high stress tissue such as cartilage, bone, and skin.¹¹ Another collagen species is the fibril-associated collagens with interrupted triple helices, which include collagen types IX, XII, XIV, and XVI. These collagens interact with fibrillar collagens and other extracellular molecules including aggrecan, cartilage oligomeric matrix protein, and other sulfated proteoglycans.¹¹ Collagen types VIII and X are non-fibrillar, short-chain collagens, and type X collagen is the most abundant extracellular matrix molecule expressed by hypertrophic chondrocytes during endochondral ossification.¹² The major collagens of articular cartilage are fibrillar collagen types II, IX, X, and XI. In developing cartilage, the core fibrillar network is a cross-linked copolymer of collagens II, IX, and XI.¹³ Mutations in genes that encode these collagens and proteins involved in their processing result in various skeletal dysplasias and highlight the importance of these molecules in skeletal development.

Classification and Nomenclature

As mentioned earlier, in the 1970s, there was recognition of the genetic and clinical heterogeneity of heritable disorders of connective tissue and a new awareness of the complexity of these disorders. As a result, there have been multiple attempts to classify these disorders in a manner that clinicians and scientists could use effectively to diagnose and determine their pathogenicity (International Nomenclature of Constitutional Diseases of Bone, 1970, 1977, 1983, 1992, 2001, 2005, 2010). The initial categories were purely descriptive and clinically based. With the more recent explosion in determining the genetic basis of these

Figure 105-1 Classification of chondrodysplasias based on radiographic involvement of the long bones (A-C) and vertebrae (side view of vertebral bodies and spinous processes in D and E). A and D are normal, B is an epiphyseal abnormality, C is a metaphyseal abnormality, and E is a “spondylo-” abnormality.

diseases, the classification has evolved into one that combines the older clinical one (including the eponyms and Greek terms) and blends these disorders into families that share a molecular basis or pathway. The most recent updated classification can be found at www.isds.ch. Some of the chondrodysplasia families are listed in Table 105-1.

The most widely used method for differentiating the skeletal disorders has been through the detection of skeletal radiographic abnormalities. Radiographic classifications are based on the different parts of the long bones that are abnormal (epiphyses, metaphyses, and diaphyses) (Figure 105-1). These epiphyseal, metaphyseal, and diaphyseal disorders can be differentiated further depending on whether or not the spine is involved (spondyloepiphyseal, spondylo-metaphyseal, or spondyloepimetaphyseal dysplasias). The classes of these disorders can be differentiated further into distinct disorders on the basis of other clinical and radiographic findings.

Clinical Evaluation and Features

The skeletal dysplasias are generalized disorders of the skeleton and usually result in disproportionate short stature. Affected individuals usually present because they are disproportionately short. This finding needs to be documented on the appropriate growth curves for gender and ethnicity if possible. As a generalization, most individuals with disproportionate short stature have skeletal dysplasias, and individuals with proportionate short stature have endocrine, nutritional, or prenatal-onset growth deficiency or other disorders. Exceptions to the rule include congenital hypothyroidism, which is associated with disproportionate short stature, and disorders such as osteogenesis imperfecta (OI) and hypophosphatasia can be associated with normal body proportions.

A disproportionate body habitus may not be immediately visible on physical examination. Anthropometric dimensions such as upper-to-lower segment (U/L) ratio, sitting height, and arm span must be measured when considering the possibility of a skeletal dysplasia and should be measured in centimeters. Sitting height is an accurate measurement

AD, autosomal dominant; AR, autosomal recessive; CATSHL, camptodactyly, tall stature, and hearing loss syndrome; OSMED, otospondylometaphyseal dysplasia; SADDAN, severe achondroplasia with developmental delay and acanthosis nigricans; TRPV4, transient receptor potential vanilloid 4; XLR, X-linked recessive; XLD, X-linked dominant.

of head and trunk length, but it requires special equipment for precise measurements. U/L ratios are easy to obtain and provide an accurate measurement of proportion. The lower segment is measured from the symphysis pubis to the floor at the inside of the heel. The upper segment is measured by subtracting the lower segment measurement from the total height. McKusick¹⁴ has published standard U/L segment ratios for whites and African-Americans across ages. An average-height white child 8 to 10 years old has a U/L segment ratio of approximately 1 and as an adult has a U/L segment ratio of 0.95. Individuals presenting with disproportionate short stature have altered U/L segment ratios depending on whether they have short limbs, short trunk, or both. An individual with short limbs and normal trunk has an increased U/L segment ratio, and an individual with normal limbs but short trunk has a diminished U/L segment ratio (Figure 105-2). Another means of determining if there is disproportion is based on arm span measurements, which are close to total height in an average-proportioned individual. A short-limbed individual has an arm span considerably shorter than the height.

As in any disorder that has a genetic basis, it is crucial to obtain an accurate family history. This should include any history of previously affected children or parental consanguinity. The skeletal dysplasias are genetically heterogeneous and can be inherited as autosomal dominant, autosomal recessive, X-linked recessive, and X-linked dominant disorders, and rarer genetic mechanisms of disease including germline mosaicism, uniparental disomy, and chromosomal rearrangements have been seen.¹⁵⁻¹⁸ For many patients and families, accurate diagnosis and recurrence risk can have a significant impact on their reproductive decisions. Another consideration for patients with short stature is that there is increased nonrandom mating, which leads to reproductive outcomes that have been previously unknown.^{19,20} Homozygous achondroplasia is lethal, and many newborns who inherit two dominant mutations (compound heterozygotes) die early with severe abnormalities of the skeleton.²¹ It is also important to obtain an accurate history relative to the onset of short stature and whether it developed immediately in the postnatal period or was noticed at age 2 or 3. Of the 450 skeletal dysplasias, approximately 100 of them have onset in the prenatal period, but

many affected individuals do not develop disproportionate short stature and joint discomfort until childhood.^{22,23}

A detailed physical examination may reveal a diagnosis or help differentiate the most likely group of possible diagnoses. It is crucial when disproportion and short stature have been established and the limbs are involved to determine which segment is involved: upper segment (rhizomelic—humerus and femur); middle segment (mesomelic—radius, ulna, tibia, and fibula); and distal segment (acromelic—hands and feet). Numerous head and facial dysmorphisms are seen in the skeletal disorders. Affected individuals frequently have disproportionately large heads. Frontal bossing and flattened nasal bridge are characteristic of achondroplasia, one of the most common skeletal dysplasias.²⁴ Cleft palate and micrognathia are commonly found in the type II collagen abnormalities, abnormally flattened midface with

Figure 105-2 Upper segment length/lower segment length (U/L) in 8- to 10-year-old individuals with short limb and short trunk dwarfism. The child on the left has short limbs and an increased U/L ratio; the child on the right has a short trunk and reduced U/L ratio.

a turned-up nose is frequently found in the chondrodysplasia punctata disorders,²⁵ and abnormal swollen pinnae are seen in diastrophic dysplasia.²⁶ Individuals with skeletal dysplasias should be screened for ophthalmologic and hearing abnormalities because many of these disorders are associated with eye abnormalities and hearing loss.

Further evaluation of the hands and feet can lead to further differentiation of these disorders. Postaxial polydactyly is characteristically found in chondroectodermal dysplasia and the short-rib polydactyly disorders (see [Table 105-1](#)). Short, hypermobile, radially displaced thumbs are seen in diastrophic dysplasia. Nails can be abnormally hypoplastic in chondroectodermal dysplasia and short and broad in cartilage hair hypoplasia. Clubfeet may be seen in many disorders including Kniest dysplasia, spondyloepiphyseal dysplasia congenita, Larsen syndrome, varying forms of osteogenesis imperfecta, and diastrophic dysplasia. Bone fractures occur most commonly in two types of disorders—those that result from undermineralized bone (OI, hypophosphatasia, achondrogenesis IA), or those that result from overmineralized bone (osteopetrosis syndromes and dysosteosclerosis).

Organ systems other than the skeleton can be involved, although rarely. Congenital cardiac defects are seen in chondroectodermal dysplasia (atrial septal defects), the short-rib polydactyly disorders (complex outlet defects including isolated ventricular septal defects), and Larsen syndrome (ventricular septal defects). Gastrointestinal anomalies are rare among the skeletal disorders, but congenital megacolon can be seen in cartilage hair hypoplasia, malabsorption syndrome in Schwachmann-Diamond syndrome, and omphaloceles in otopalatodigital syndrome and atelosteogenesis I.

Diagnosis and Testing

After obtaining a thorough family history and physical examination, the next step is to obtain a full set of skeletal radiographs. A full series of skeletal views includes anterior,

lateral, and Towne views of the skull; anterior and lateral views of the entire spine; and anteroposterior views of the pelvis and extremities, with separate views of the hands and feet, especially after the newborn period. Most of the important clues to diagnosis are in skeletal radiographs that are obtained before puberty. When the epiphyses have fused to the metaphyses, determining the precise diagnosis can be extremely challenging. If an adult is evaluated, all attempts should be made to obtain any available childhood radiographs. Many subtle clues in these skeletal radiographs can lead to precise diagnosis. Demonstrating punctate calcifications in the areas of the epiphyses in the chondrodysplasia punctata disorders, multiple ossification centers of the calcaneus in more than 20 disorders,²⁷ and the type of hand shortening can aid in differentiating many disorders.

After obtaining radiographs, close attention should be paid to the specific parts of the skeleton (spine, limbs, pelvis, skull) involved and to the location of the lesions (epiphyses, metaphyses, and vertebrae) ([Figure 105-3](#)). As mentioned earlier, these radiographic abnormalities can change with age, and if available, radiographs across a few years or decades aid in diagnosis. Fractures can be seen in OI (all types) ([Figure 105-4](#); see [Table 105-1](#)) and severe hypophosphatasia. In older individuals, fractures may be seen in disorders associated with increased mineralization such as the osteopetrosis syndromes and dysosteosclerosis. When a thorough evaluation of the radiographs reveals abnormalities, but a diagnosis still cannot be made, resources are available. The International Skeletal Dysplasia Registry and European Skeletal Dysplasia Network are available to provide diagnosis for these rare disorders.

Morphologic studies of chondro-osseous tissue have revealed specific abnormalities in many of the skeletal dysplasias.²⁸⁻³⁰ In these disorders, histologic evaluation of chondro-osseous morphology can aid in making an accurate diagnosis, and absence of histopathologic alterations can rule out diagnoses. These studies need to be done on cartilage growth plate, and although commonly performed on perinatal lethal skeletal disorders at autopsy, obtaining

Figure 105-3 Radiographs showing abnormalities in the chondrodysplasias, specifically pseudoachondroplasia. **A**, Irregular metaphyses and small epiphyses. **B**, Small, rounded vertebrae with anterior beaking.

Figure 105-4 Radiographs illustrating skeletal differences among variants of osteogenesis imperfecta (OI). **A**, Dominant OI—mild, with minimal deformity. **B**, Moderate OI—mild epiphyseal dysplasia. **C**, Severe OI—marked diaphyseal narrowing and widening of the metaphysis with severe epiphyseal dysplasia. Lethal OI is not illustrated.

growth plate histology on individuals with nonlethal disorders is difficult. If affected individuals (children) are undergoing surgery, an iliac crest biopsy specimen can be evaluated.

Histomorphology studies done on these disorders have led to important insights on the pathogenesis of these disorders. On morphologic grounds, the chondrodysplasias can be broadly classified into disorders (1) that have a qualitative abnormality in endochondral ossification, (2) that have abnormalities in cellular morphology, (3) that have abnormalities in matrix morphology, and (4) in which the abnormality is primarily localized to the area of chondro-osseous transformation. In thanatophoric dysplasia, there is a defect in endochondral ossification with a short, almost hypertrophic zone; shortened proliferative zone; and overgrowth of the periosteum. In pseudoachondroplasia, there is a distinct lamellar pattern (alternating electron-dense and electron-lucent lamellae) in the rough endoplasmic reticulum of chondrocytes (Figure 105-5) and a grossly abnormal matrix in diastrophic dysplasia, which leads to a characteristic ring around the chondrocytes. All of these findings are characteristic and diagnostic for these disorders and illustrate how

Figure 105-5 Electron micrograph of a chondrocyte from an individual with pseudoachondroplasia. Note the characteristic lamellar pattern in the rough endoplasmic reticulum.

morphology studies can have an integral part in the investigation of these disorders.

There has been significant progress in gene identification in these disorders, which has impact for affected individuals. As illustrated in Table 105-1, for disorders in which the gene is identified, molecular diagnostic testing is potentially available. Molecular diagnosis can be used to confirm a clinical and radiographic diagnosis, predict carrier status in families at risk for a recessive disorder, and, for some individuals, allow for prenatal diagnosis of at-risk fetuses. Because these are rare disorders, commercial testing is not always readily available; however, GeneTests (www.genetests.org) is a publically funded medical genetics website developed for physicians that provides information on diseases and available genetic testing.

Management and Treatment

The optimal management of this diverse set of disorders requires an understanding of the medical, skeletal, and psychosocial consequences.³¹ This is often best accomplished by centers that have a multidisciplinary approach, which includes adult and pediatric physicians, orthopedists, rheumatologists, otolaryngologists, neurologists, neurosurgeons, and ophthalmologists who are committed to the care of these patients.

Most medical complications in these disorders result from orthopedic complications, and they vary depending on the specific disorder. In disorders associated with significant odontoid hypoplasia such as Morquio disease, type II collagenopathies, metatropic dysplasia, and Larsen syndrome, flexion-extension films should be monitored at regular intervals to assess for C1-C2 subluxation. Many experts in the field now believe that all individuals with skeletal dysplasias should have evaluation of their cervical spine, regardless of diagnosis. If there is evidence for subluxation, surgery for C1-C2 fixation is indicated. Genu varum—lateral curvature of the lower extremity—is common in many skeletal disorders caused by overgrowth of the fibula; this causes knee or ankle pain in many individuals, especially children, and correction by osteotomy should be

considered. Children and adults with skeletal dysplasias should have regular eye and hearing examinations because they are at increased risk for myopia, retinal degeneration, glaucoma, and hearing loss depending on the disorder.

Frequently, patients with these disorders have significant joint pain and in some cases joint limitations. Because most of these disorders result from mutations in genes crucial to cartilage function, the cartilage at the joint surfaces may not provide adequate support and cushioning function. Many of these patients seek attention for joint pain. Evaluation should include radiographs and magnetic resonance imaging (MRI), when appropriate, to determine the etiology of the pain. In some disorders such as the type II collagenopathies, pseudoachondroplasia, multiple epiphyseal dysplasia, and cartilage hair hypoplasia, by adulthood, so little cartilage remains at the knee or hips that joint replacement is indicated for pain relief. Lastly, overweight in adults with short stature is an ongoing issue and contributes to inactivity, loss of function, adult-onset diabetes, hypertension, and coronary disease.²⁹

Achondroplasia

Achondroplasia is the most common of the nonlethal skeletal dysplasias (approximately 1 in 20,000) and serves as an example on how to approach these disorders. Most affected individuals are of normal intelligence, have a normal life span, and lead independent and productive lives. The mean final height in achondroplasia is 130 cm for men and 125 cm for women; specific growth charts have been developed to document and track linear growth, head circumference, and weight in these individuals.^{32,33}

In early infancy, there is potentially serious compression of the cervicomedullary spinal cord secondary to a narrow foramen magnum, cervical canal, or both. Clinically, these infants have central apnea, sleep apnea, profound hypotonia, motor delay, emesis while forward positioned in car seats, or excessive sweating. MRI with flow studies is necessary to document the obstruction; if present, obstruction requires decompressive surgery.³⁴ Other complications include nasal obstruction, venous distention, thoracolumbar kyphosis, and hydrocephalus in a few individuals.³⁵

From early childhood, and as children begin to walk around 22 to 24 months, they develop several orthopedic manifestations, which include progressive bowing of the legs owing to fibular overgrowth, lumbar lordosis, and hip flexion contractures. Recurrent ear infections can lead to chronic serous otitis media and deafness. Tympanic membrane tube placement is indicated in many of these patients. Craniofacial abnormalities lead to dental malocclusion, and appropriate treatment is necessary. In adults, the main potential medical complication is impingement of the spinal root canals. This complication can be manifested by lower limb paresthesias, claudication, clonus, or bladder or bowel dysfunction. It is crucial that these complaints are addressed because without appropriate decompression surgery, spinal cord paralysis may result.³⁶

Growth hormone has not been effective in increasing height in this disorder.³³ Surgical limb lengthening has been employed successfully to increase limb length by 12 inches,³⁷ but this technique needs to be done during the teen years and is performed over a 2-year period and is associated with

complications. Recent advances in the molecular understanding underlying achondroplasia have identified molecular targets to potentially treat the disorder, thus improving height and orthopedic complications. Achondroplasia results from heterozygosity for mutations in the gene that encodes fibroblast growth factor receptor 3 (FGFR3). The mutation causes constitutive activation of the receptor leading to increased MAPK signaling with elevated levels of ERK1/2 phosphorylation. Molecules targeted to the tyrosine kinase domain of the receptor and those that diminish ERK signaling have shown efficacy in tissue and animal models. Throughout their lives, individuals with achondroplasia and other skeletal dysplasias and their families experience various psychosocial challenges.³⁸ These challenges can be addressed by specialized medical and social support systems. Interactions with advocacy groups such as Little People of America (www.lpaonline.org) can provide emotional support and medical information.

Biochemical and Molecular Abnormalities

Similarities in clinical and radiographic findings and histomorphology have placed bone dysplasia into families.³⁹⁻⁴¹ These families share common pathophysiologic or pathway mechanisms. In recent years, there has been an explosion in understanding of the basic biology of these disorders. This explosion has resulted from the successful human genome project, which improved various methodologies including candidate gene approach, linkage analysis, positional cloning, human/mouse synteny, array comparative genomic hybridization, and massive parallel sequencing (whole exome or whole genome analyses) allowing for identification of the disease genes (see [Table 105-1](#)). With gene discovery in the vast number of these osteochondrodysplasias, these genes can be placed into several categories designed to understand their pathogenesis: (1) defects in extracellular proteins; (2) defects in metabolic pathways (enzymes, ion channels, and transporters); (3) defects in folding and degradation of macromolecules; (4) defects in hormones and signal transduction; (5) defects in nuclear proteins; (6) defects in oncogenes and tumor-suppressor genes; (7) defects in RNA and deoxyribonucleic acid (DNA) processing molecules; (8) defects in intracellular structural and organelle proteins; (9) microRNAs; and (10) genes of unknown function.² There are still skeletal dysplasias for which the gene and mechanism of disease are unknown. Following are descriptions of some of the molecular mechanisms involved in the skeletal dysplasias.

DEFECTS IN EXTRACELLULAR STRUCTURAL PROTEINS

Type II Collagen and Type XI Collagen

Because type II collagen was found primarily in cartilage, the nucleus pulposus, and the vitreous of the eye, it was hypothesized that skeletal disorders with significant spine and eye abnormalities would result from defects in type II collagen. Type II collagen defects have been identified in a spectrum of disorders ranging from lethal to mild arthropathy, which include achondrogenesis II, hypochondrogenesis, spondyloepiphyseal dysplasia congenita,

spondyloepimetaphyseal dysplasia, Strudwick type, Kniest dysplasia, Stickler syndrome, spondyloperipheral dysplasia, and “precocious” familial arthropathy. These disorders are referred to as type II collagenopathies, and they all result from heterozygosity for mutations in *COL2A1*.^{42,43} Biochemical analysis of cartilage derived from these individuals shows electrophoretically detectable abnormal type II collagen. Type I collagen is not normally present in cartilage, but in the presence of abnormal type II collagen there is increased type I collagen in the growth plate.

Mutations that result in a substitution for a triple helical glycine residue seem to be the most common type of mutation.⁴⁴ There are some correlations between the location of the mutation and the disease phenotype. In spondyloepiphyseal dysplasia, the glycine substitutions are scattered throughout the molecule; however, in Kniest dysplasia, the mutations are in the more amino-terminal end of the molecule.^{44,46} Stickler syndrome, a disorder of mild short stature, arthropathy, and high-grade myopia (see Table 105-1), is genetically heterogeneous and results from mutations in *COL2A1* and *COL11A1*, and nonocular forms result from mutations in *COL11A2*.^{47,48} In Stickler syndrome, the *COL2A1* and *COL11A1* mutations tend to be nonsense mutations resulting in premature translation stop codons; however, patients with *COL11A1* mutations tend to have a more severe eye phenotype and hearing loss than patients with *COL2A1* mutations.

Individuals heterozygous for various *COL11A2* mutations⁴⁹ have a nonocular form of Stickler syndrome, consistent with the absent expression of *COL11A2* in the vitreous humor. Otospondylomegaepiphyseal dysplasia is a rare autosomal recessive disorder caused by loss of function mutations in *COL11A2*.⁵⁰ This disorder has radiographic similarities to Kniest dysplasia but is associated with profound sensorineural hearing loss and lack of ocular involvement. Recent discoveries have extended the spectrum of disease for type XI collagen. Autosomal recessive fibrochondrogenesis, a severe skeletal dysplasia, highly associated with lethality, results from mutations in the two genes that encode type XI, *COL11A1* and *COL11A2*.^{51,52} Type II and

XI collagens form a heterotypic fibril in the cartilage matrix and not surprisingly, there is significant clinical overlap in the disorders due to mutation in the genes that encode these collagens.

Cartilage Oligomeric Matrix Protein

Heterozygosity for mutations in cartilage oligomeric matrix protein leads to pseudoachondroplasia and multiple epiphyseal dysplasia.⁵³ Cartilage oligomeric matrix protein is a member of the thrombospondin family of proteins and consists of an epidermal growth factor domain and calcium binding, calmodulin domain.⁵⁴ In pseudoachondroplasia and multiple epiphyseal dysplasia, disease-producing mutations occur in the calmodulin domain, with a few in the globular carboxy-terminal domain (Figure 105-6). As opposed to pseudoachondroplasia, multiple epiphyseal dysplasia results from heterozygosity for mutations in numerous genes (*COL9A1*, *COL9A2*, *COL9A3*, and *MATRILIN3*), and there is a recessive form due to mutations in the *DTDST* gene. Both these disorders are associated with significant early destruction of cartilage with many affected individuals undergoing hip and knee replacements at an early age.

Defects in Metabolic Pathways

Defects in metabolic pathways comprise defects in enzymes, ion channels, and transporters essential for cartilage metabolism and homeostasis. An example is the diastrophic dysplasia group (see Table 105-1), a spectrum of disorders (lethal to mild short stature) resulting from mutations in the *DTDST* (*SLC26A2*) gene. These disorders result from a varying defect in the degree of sulfate uptake or transport into chondrocytes.⁵⁵ Lack of adequate intracellular sulfate affects the normal post-translational modification of proteoglycans and leads to abnormal chondrogenesis that is proportional to the degree of transporter compromise.⁵⁰ Affected individuals suffer from severe degenerative joint disease.

Figure 105-6 Diagram of the cartilage oligomeric matrix protein delineating the domains—NH₂, amino terminus, epidermal growth factor-like (EGF-like), calmodulin-like, carboxy-terminus (COOH), pseudoachondroplasia (PSACH), and multiple epiphyseal dysplasia (MED). Amino acid substitutions are listed below the molecule.

Defects in Intracellular Structural Proteins

Intracellular proteins are ubiquitously expressed proteins; the finding that mutations in the genes encoding filamin A and filamin B produced primarily skeletal disorders was surprising.⁵⁶⁻⁵⁸ The filamins are cytoskeleton proteins involved in multicellular processes including providing structure to the cell, facilitating signal transduction and transport of small solutes, allowing communication between the intracellular and extracellular environment, and participating in cell division and motility. Defects in these genes have a profound effect on the skeleton ranging from absence of bone formation to significant joint dislocations. The mechanisms by which these mutations produce disease are unclear, though alterations in the cellular and organelle functions are beginning to be elucidated.⁵⁹

Defects in Membrane Channels

Calcium homeostasis is critical for cartilage and bone.^{59,60} TRPV4, or transient receptor potential cation channel subfamily V member 4, is a cation channel that mediates calcium influx in response to numerous stimuli. The importance of this channel has been demonstrated because it produces a vast spectrum of autosomal dominant skeletal disorders including lethal metatropic dysplasia, non-lethal metatropic dysplasia, spondyloepiphyseal dysplasia, Kozłowski type, and brachyolmia.⁶¹⁻⁶³ In addition, heterozygosity for mutations in *TRPV4* also causes neuromuscular diseases without notable bony manifestation that include hereditary motor and sensory neuropathy type IIC, congenital spinal muscular atrophy, and scapulohumeral spinal muscular atrophy.⁶⁴⁻⁶⁶ The mechanism by which these mutations scattered throughout the molecule produce such divergent phenotypes is unclear but supports some common pathway in tissues of mesenchymal origin.

Summary

Although these osteochondrodysplasias are rare disorders, affected individuals have significant skeletal complications throughout their lives, first owing to patterning defects, then effects on linear growth, and finally loss of normal structural cartilage as a cushion later in life. The explosion in delineating the molecular defects has shown the complexity of cartilage as a tissue and the large number of cellular processes necessary for a normal skeleton.

OSTEOGENESIS IMPERFECTA

OI is a heritable disorder of bone and was one of the first disorders hypothesized to be a defect in collagen by McKusick.¹ Although an osteochondrodysplasia, OI is discussed separately from the chondrodysplasias delineated previously. OI is a generalized disorder of connective tissue that predominantly affects the skeletal system⁶⁷ and affects numerous individuals (estimates at about 1 in 20,000 individuals).

Initially, there were four types of recognized OI in the clinical classification of Sillence.⁶⁸ There are now seven well-recognized forms of OI, and through recent gene discoveries it is apparent that a clinical classification system is

no longer useful. Because there is enormous clinical variability in these types, the subtypes are discussed separately using historical classifications, but many experts advocate using the terms mild, moderate, and severe (Table 105-2). These disorders all share the same phenotypic finding of hypomineralization of the skeleton.

Mild Osteogenesis Imperfecta (Type I)

Affected individuals with OI type I disease have mild disease in terms of clinical course, the extent of skeletal deformity, and the radiologic appearance of the skeleton (see Figure 105-4A and Table 105-2). They also account for most individuals with OI. Individuals are usually short for their age or their unaffected family members. Many of these individuals experience numerous fractures, especially in childhood; children with OI type I may have 20 fractures by the age of 5.

The disorder is autosomal dominant, and in many cases the individual is the first affected in the family. There is mild facial dysmorphism in OI type I with a mild triangular facial shape. The blue sclerae become gray-to-pale blue in adulthood. Arcus senilis not related to lipid abnormalities may occur in some patients. Other reported ocular defects include scleromalacia, keratoconus, and retinal detachment.⁶⁹ Teeth frequently show dentinogenesis imperfecta owing to the effects of mutation on the tooth dentin. The deciduous and permanent teeth have an opalescent and translucent appearance, which tends to darken with age. The enamel is normal, but the dentin is dysplastic; chipping of enamel occurs, and the teeth are subjected to erosion and breakage. Teeth of affected individuals appear discolored or gray. This finding varies in the disorder but does co-segregate in families with OI. During the second and third decades of life, a characteristic high-frequency sensorineural or mixed hearing loss can be detected.⁷⁰ The incidence of mitral valve prolapse is not increased in these patients compared with the population at large, but individual kindreds with increased diameter of the aortic root or patients with aortic regurgitation have been reported.⁷¹ Many patients complain of easy bruising, and this may result from the effects of mutation on skin and the vessels below.

Mildly affected patients may not have fractures at birth, although occasionally a fracture of a clavicle or extremity occurs during delivery. Radiographically, affected newborns have wormian bones seen on lateral views of the skull, with significant osteopenia seen through the skeleton, especially the spine. After birth, the frequency of fracture depends on the child's activity, the need for immobilization after lower extremity fractures, and the attitude of the family toward independent activity. Generally, these patients may experience 5 to 15 major fractures before puberty and several minor traumatic fractures of the digits or the small bones of the feet. Characteristically, the fracture rate declines dramatically after puberty, only to increase during later life. Mild scoliosis approximating 20 degrees is common. Osteopenia is observed in vertebral bodies and the peripheral skeleton and progresses with age. In mild OI, the long bones usually heal with no significant deformity. Compared with more severe phenotypes, children with mild OI only infrequently require the insertion of intramedullary rods and almost never experience nonunion at a fracture site.

Table 105-2 Classification and Molecular Basis of Osteogenesis Imperfecta

OI	Clinical Features	Inheritance	Biochemical Abnormality	Gene
Mild (type I)	Normal stature, little or no deformity, blue sclerae, hearing loss, dentinogenesis imperfecta	AD (new mutations are common)	50% reduction in type I collagen synthesis	<i>COL1A1</i> <i>COL1A2</i>
Lethal (type II)	Lethal; minimal calvarial mineralization, beaded ribs, compressed femurs, long bone deformity	AD (new mutations; gonadal mosaicism) AR	Structural alterations of type I collagen chains—overmodification of type I collagen	<i>COL1A1</i> <i>COL1A2</i> <i>CRTAP</i> <i>P3H1</i> <i>PPBI</i>
Severe (types III and IV)	Progressively deforming bones, dentinogenesis imperfecta, hearing loss, short stature	AD AR	Structural alterations of type I collagen chains—overmodification of type I collagen	<i>COL1A1</i> <i>COL1A2</i> <i>CRTAP</i> <i>P3H1</i> <i>PPBI</i> <i>FKBP10</i> <i>SERPINH1</i> <i>SP7</i>
V	Similar to severe OI plus calcification of interosseous membrane of forearm, hyperplastic callus formation	AD	None described	Unknown
VI	Similar to type IV with vertebral compression; mineralization defect	AR	None described	<i>SERPINF1</i>
VII	Moderate to severe, with fractures at birth, early deformity and rhizomelia	AR	None described	<i>CRTAP</i>

AD, autosomal dominant; AR, autosomal recessive; *CRTAP*, cartilage-associated protein; *P3H1*, prolyl-3-hydroxylase 1; *PPBI*, cyclophilin B; *FKBP10*, FK506-binding protein 10; *SERPINH1*, Serpin Peptidase Inhibitor, Clade H, Member1; *SP7*, osterix; *SERPINF1*, Serpin Peptidase Inhibitor, Clade F, Member1.

Although osteopenia with rarefaction of the medullary space and cortical thinning are observed in radiographs, many mild OI cases can be missed on routine radiographic examination and present later in life as individuals with significant osteoporosis. Measurement of bone mineral density by dual-energy x-ray absorptiometry at any age discloses a significant decrease in bone mass.⁷² T scores (i.e., standard deviation from the young-adult mean bone mineral density) are frequently in the range of -2.5 to -4.0 at the lumbar spine or proximal femur, consistent with the diagnosis of osteoporosis as defined by the World Health Organization. Low bone mineral density in children with recurrent fractures may assist in identifying children with OI.

Molecular Pathology

As in many other OI phenotypes, OI type I or mild OI is the result of mutations affecting the *COL1A1(I)* and *COL1A2(I)* polypeptide chains of type I collagen. Cultured fibroblasts from individuals with mild OI synthesize low amounts (approximately one-half) of the expected amounts of type I collagen. The molecular basis for the low production of type I collagen seems to be diminished activity of one of the *COL1A1(I)* or *COL1A2(I)* collagen alleles. Many of the reported mutations in OI type I are nonsense and frameshift mutations and are predicted to lead to premature termination codons, although there are some exceptions.^{73,74}

Lethal Osteogenesis Imperfecta (Type II)

Approximately 10% of OI patients have the severe neonatal form of the disease, lethal OI. Most cases result from sporadic mutations; however, more recently, recessive forms of

the disease have been documented.⁷⁵⁻⁷⁸ These infants present with severe bone fragility, multiple intrauterine fractures at various stages of healing, deformed extremities, and occasionally hydrops fetalis (Figure 105-7). Radiographic features include wormian bones, multiple fractures, crumbled bones, and characteristic beading of the ribs owing to healing callus formation. There is a subtype of the lethal form, OI type IIC, which is autosomal recessive and is differentiated by the absence of beaded ribs (thin ribs) and a different molecular basis of disease.

Molecular Pathology

Most cases occur de novo, as new dominant mutations; however, autosomal recessive forms have been established, as has recurrence based on germline mosaicism.⁷⁹⁻⁸² The biochemical abnormality in lethal OI is the inability to synthesize, modify, and secrete normal type I collagen.⁸³ As a result, the amount of type I collagen in bone is low, much of the secreted collagen is abnormally overmodified, and the quantity of the minor collagen types III and V is high. Bone collagen fibers are thinner than normal, and at the intracellular level, type I collagen is retained within dilated endoplasmic reticulum.

Similar to other forms of OI, mutations in the genes encoding *COL1A1* and *COL1A2A* lead to the dominant form or de novo form of lethal OI.⁸⁴ Single glycine substitutions with the Gly-X-Y triplet of either *COL1A1* or *COL1A2* lead to this form of OI, as do some small deletions, all producing severe effects on the triple helix. The recessive form accounts for a few of these cases and results from mutations in the genes encoding either *CRTAP* (cartilage-associated protein), *P3H1* (prolyl-3-hydroxylase 1), and *cyclophilin B* (*PPBI*).⁷⁵⁻⁷⁸ These molecules form a complex that hydroxylates (add an -OH group) to a third position

Figure 105-7 Radiograph of lethal osteogenesis imperfecta (type II) showing poorly mineralized calvaria; bent, crumbled bones; and ribs with fractures and callus formation.

residue at proline 986 (Pro986). This modification of a single residue stabilizes the collagen helix.⁷⁵⁻⁷⁸ Nonsense or frameshift mutations predicted to lead to premature termination codons and absent function of *CRTAP*, *P3H1*, and *PPBI* produce this form of OI.

Severely Deforming Osteogenesis Imperfecta (Including Type III and Type IV)

The deforming variant of OI is the classic form of OI. Similar to lethal OI (OI type II), most cases are inherited as autosomal dominant (or a *de novo* mutation), although recurrent cases based on autosomal recessive inheritance owing to *CRTAP* or *P3H1* mutations have been described more recently, as well as other recently discovered genes, *FKBP10*, *HSP47*, and *SP7*.⁷⁹⁻⁸¹ This variant is characterized by severe deformity of the limbs and marked kyphoscoliosis, thorax deformity, and significant short stature. The extent of growth retardation is remarkable, and in many adults the height may not surpass 3 feet (90 to 100 cm). Abnormal cranial molding occurs in utero and during infancy, producing frontal bossing and a characteristic triangular-shaped facies. Radiographically, wormian bones and delayed closure of the fontanelles may be observed well into the first decade.

Pulmonary function can be diminished because of distortion of the spine and thorax, and this can progress over time and lead to restrictive lung disease and sleep apnea. Because of diminished vital capacity, pulmonary insufficiency is a leading cause of death in patients with OI type III. Many patients with scoliosis greater than 60 degrees develop

respiratory compromise and need pulmonary investigations. Many of these individuals need supplemental oxygen.

Platybasia secondary to soft bone at the base of the skull may cause the external ear canals to slant upward as the base of the skull sinks on the cervical vertebrae; this may lead to communicating or obstructive hydrocephalus, cranial nerve palsies, and upper and lower motor neuron lesions. Headache, diplopia, nystagmus, cranial nerve neuralgia, decline in motor function, urinary dysfunction, and respiratory compromise are complications of basilar invagination.⁸⁵ As opposed to OI type I, most affected OI type III patients have white sclerae as adults. Approximately 25% of patients with autosomal dominant type III OI have dentinogenesis imperfecta, necessitating constant dental care throughout childhood, though this is not true of the recessive forms of this severe form of OI. Severe hearing impairment occurs in 10% of patients, although milder degrees of hearing loss are more common.

The skeleton in these patients has significant osteopenia, leading to multiple fractures in the upper and lower extremities and vertebral bodies, particularly before puberty. In contrast to OI type I, in which fractures tend to heal without deformity, fractures in OI type III frequently lead to skeletal deformity. Radiographs of the skeleton reveal marked osteopenia, thinning of cortical bone, narrowing of the diaphysis, and widening of the metaphysis, which merges into a dysplastic epiphyseal zone filled with whorls of partially calcified cartilage (i.e., popcorn deformity) (see Figure 105-4C). Osteoporosis leads to collapse of vertebral end plates contributing to worsening kyphoscoliosis. Pectus excavatum or pectus carinatum adds to thoracic deformity. In addition, lack of weight bearing increases the severity of osteoporosis and increases the risk of fracture. Many individuals become wheelchair bound at an early age or walk with mechanical assistance.

Clinically, the phenotype of patients with moderately severe OI (OI type IV) falls between the milder and severe forms of OI. In most cases, this form of OI is inherited in an autosomal dominant fashion. Fractures occur rarely at birth, and some patients may not have an initial fracture until later in the first decade. The extent of skeletal deformity involving the spine, thorax, and extremities is usually intermediate between mild and severe, but these patients have short stature and frequently these patients have scoliosis. Patients may have some mild facial dysmorphisms and hearing loss. Most fractures occur during childhood and may reoccur during the postmenopausal period in women or in men older than age 50 years. Long bone deformity tends to develop after fractures, which may lead to a difficulty in ambulation. Radiographs of the long bones and vertebral bodies show marked osteopenia with vertebral collapse. Although there is marked cortical thinning, bowing, and coarsening of trabeculae, the overall architecture of the bone is normal (see Figure 105-4B).

Molecular Pathology

The molecular basis of OI type III and OI type IV is similar to OI type II. Most cases result from heterozygosity for mutations in *COL1A1(I)* and *COL1A2*.^{86,87} These mutations are glycine substitutions scattered throughout the triple helix and in-frame deletions.⁶⁸ As in OI type II, familial

recurrences result from mutations in *CRTAP*, *P3H1*, and *PPBI*, which cause autosomal recessive forms of OI. Recently other genes producing autosomal recessive forms of severe OI have been identified including *FKBP10*, *HSP47*, and *SP7*.⁷⁹⁻⁸¹ There may be subtle clinical distinctions between the recessive forms of the disease, though radiographic abnormalities are quite similar. Clinical suspicion of the recessive form of the disease should be considered if there is a family history of recurrence.

Osteogenesis Imperfecta Type V (Moderate to Severe)

OI type V was reported in 2000 as a variant within the heterogeneous group classified under OI type IV.⁸⁸ In the initial report of seven OI patients, the phenotype was distinguished by the following criteria: moderate fracture history, hyperplastic callus formation, limitation in forearm pronation and supination as a result of intramembraneous bone formation at the joint, normal sclerae, and no dentinogenesis imperfecta. Bone biopsy specimens showed a meshlike appearance of irregularly spaced lamellae, different from the woven bone seen in OI types II, III, and IV. The etiology of this rare form has not been established.

Osteogenesis Imperfecta Type VI (Moderate to Severe)

The brittle bone phenotype OI type VI was also reported among the heterogeneous OI type IV group of patients. Characteristic among the eight subjects was the occurrence of a first fracture at an early age (4 to 18 months old).^{89,90} The bone is severely brittle, and affected patients have white sclerae. All patients had vertebral compression fractures, and patients showed elevated serum alkaline phosphatase levels. The gene for this form of OI has been recently identified, pigment epithelium-derived factor (*PEDF*), also known as serpin F1 (*SERPINF1*), an antiangiogenic protein (unpublished data).

Osteogenesis Imperfecta Type VII (Moderate to Severe)

In addition to OI types V and VI, Glorieux reported on an autosomal recessive form of OI and used the designation OI type VII.⁹⁰ This form occurred with a small genetic isolate among the First Nations community in northern Quebec, Canada (S89). The phenotype includes fractures at birth, blue sclerae, osteopenia, rhizomelia, and deformities of the lower extremities. The disorder has been localized to chromosome 3p22-24 and has been shown to result from a hypomorphic allele in *CRTAP*.⁶³ The identification of the molecular basis of OI type VII changed the molecular view of the basis of disease with the identification of recessively inherited gene defects.

Histopathology of Bone in Osteogenesis Imperfecta

The range of histologic appearances of bone in the different OI phenotypes is as variable as the clinical phenotypes. Undermineralization and overmineralization of bone have

been recognized within the same specimen.⁹¹ Bone histomorphology appears relatively normal in OI type I, but osteopenia secondary to thin lamellar plates and diminished cortical width is evident. Immature woven bone and lamellar disarray are characteristic of more severe OI phenotypes.⁹²

Treatment

Over the years, there have been multiple attempts to treat OI with a variety of vitamins, hormones, and drugs, none of which has been successful. The list includes administration of mineral supplements, fluoride, androgenic steroids, ascorbic acid, and vitamin D. During the past decade, bisphosphonates administered parenterally or orally to children and adults have shown favorable results. The bisphosphonate pamidronate administered intravenously increased bone mass, decreased skeletal pain, and decreased fracture incidence in children with severe OI.⁹³ Similar results involving cyclic administration of pamidronate have been reported by other investigators.⁹⁴ Dosage regimens in different series for children and adults range from 1 to 3 mg/kg, administered intravenously at 2- to 4-month intervals; lower dosage regimens also have been reported.⁹⁴ Generally, reports indicate a significant increase in bone mass in children and a decrease in fracture rate. The effect is most marked in the spine, where vertebral remodeling may improve vertebral height. Metabolic studies have shown a decrease in serum ionized calcium and increase in serum parathyroid hormone.

Urinary excretion of N-telopeptide as an index of bone resorption decreased from 61% to 73%. The major side effects of intravenous bisphosphonate treatment include the acute-phase response (24 hours after infusion) and the occurrence of otitis and vestibular imbalance in a few patients. The currently recommended treatment regimen includes the use of a bisphosphonate, with adequate calcium and vitamin D supplementation to avoid the occurrence of hypercalciuria and to maintain normal serum vitamin D levels. Newer treatments for osteoporosis such as the RANK ligand inhibitor, denosunab, and antisclerostin antibody may hold promise for treatment of patients with OI.

The use of surgery to correct deformities and to facilitate weight bearing has been the subject of several reviews.⁹⁵ Multiple osteotomies and realignment of a deformed bone over intramedullary rods is an option for many children with severe bowing.⁹⁶ Indications include frequent fractures at the apex of the bow, impaired standing, and limb-length inequality owing to bowing.^{97,98} Expanding (telescoping) rods are best for growing children because they require fewer revisions. Spinal deformities are common and usually progressive. Surgical stabilization is most advisable in the teen years or early adulthood when patients can tolerate these complex reconstructions.⁹⁹ Early basilar invagination may be halted with prophylactic posterior fusion of the occipital-cervical junction with plate fixation.¹⁰⁰ Patients with severe brain stem compression may require anterior transoral decompression and posterior instrumented fusion. Patients with various types of OI seem to be at increased risk of premature osteoarthritis, the reasons for which are unclear.¹⁰¹ Total joint arthroplasty is usually successful in these patients, and referral is appropriate if arthroplasty is indicated.

Every child with OI benefits from appropriate rehabilitative therapy.^{102,103} Bracing with lightweight plastics as the child begins to walk can minimize microfracture and bowing of the upper femurs. Muscle-strengthening exercises are essential as primary care and after immobilization for fracture. Perhaps the most beneficial programs have been developed around swimming, preferably in heated pools, and as part of continuous rehabilitative medical care.

EHLERS-DANLOS SYNDROME

The heterogeneous group of disorders grouped together as EDS illustrates the genetic and clinical variability characteristic of the heritable disorders of connective tissue. The most cardinal feature of these disorders is the presence of joint hypermobility, associated with an increase in skin elasticity and skin fragility. In 1997, a simplified classification was proposed dividing EDS into six major clinical types. The classification includes the classic, hypermobility, vascular, kyphoscoliosis, arthrochalasia, and dermatosparaxis types, as well as several rarer EDS types grouped into “other forms.”¹⁰⁴ Clinically, EDS can be difficult to separate, however, because of considerable overlap in phenotype findings.

Classic Type

The classic type of EDS accounts for about 80% of reported cases¹⁰⁵ and is inherited as an autosomal dominant trait. Originally, EDS was classified as types I and II, and now these types are classified as the classic form, although these subclassifications are still in use. Previously, types I and II EDS were distinguished from each other on the basis of joint laxity and skin fragility, which are less severe in type I than in type II EDS. Most prototypic forms of EDS (Figure 105-8) are characterized by various degrees of hyperextensibility of large and small joints, which are classic findings in EDS. It is crucial that hyperextensibility be defined, and differentiating mild “normal” laxity from hyperextensibility can be challenging. Beighton and colleagues¹⁰⁴ have presented a clinically useful classification of joint laxity (Figure 105-9), as follows:

1. Passive dorsiflexion of the fifth digit beyond 90 degrees = 1 point for each hand
2. Passive apposition of the thumbs to the flexor surface of the radius = 1 point for each hand
3. Hyperextension of the elbows beyond 10 degrees = 1 point for each side
4. Hyperextension of the knees beyond 10 degrees = 1 point for each knee
5. Flexion of the trunk forward so that the palms can be placed flat on the ground = 1 point

A score of 5 or more points is defined as joint hypermobility.

Large joint hyperextensibility is seen in varying degrees in the classic form and decreases with age. Recurrent joint dislocations, periodic joint effusion related to trauma, and the eventual appearance of osteoarthritis pose significant management problems. Bilateral synovial thickening has been observed in EDS, along with the accumulation of small masses of crystalline material in synovial villi. It has been observed that EDS patients constituted 5% of cases in a

Figure 105-8 Ehlers-Danlos syndrome type I. Tissue elasticity, joint hypermobility, and tissue fragility are shown by the patient's ability to extend her tongue to the tip of the nose (Gorlin's sign) (A), by hyperextensibility at the knee (genu recurvatum) (B), and by characteristic “cigarette paper” or papyraceous scars of the knees and tibial skin (C). (Courtesy V. McKusick, MD.)

pediatric arthritis clinic population.¹⁰⁶ There is debate about whether affected infants may be born prematurely to affected mothers because of early rupture of amniotic membranes. Patients with EDS have characteristic facies, with a broad nasal root and epicanthal folds. They may have large, lax ears, and traction on the ears or elbows reveals skin hyperextensibility. Another sign of hypermobility is the ability to touch the tip of the tongue to the nose (Gorlin's sign). In addition, absence of the lingual frenulum is characteristic for this disorder.

In EDS, the skin has a characteristically pleasant soft or “velvety” feel that can be appreciated by stroking the forearms. Thin, atrophic corrugated and hyperpigmented scars are found on the forehead, under the chin, and on the lower extremities (known as cigarette paper or papyraceous scars), although this is not a uniform finding. Typically, skin lesions heal slowly after injury or surgery. Molluscoid pseudotumors (violaceous subcutaneous tumors ranging in size from 0.5 to 3 cm) may be palpated in tissue over pressure points on the forearms and lower extremities and may be seen on radiographs. Although many patients claim to bruise easily, ecchymoses distributed on the extremities are found only in patients with the more severe forms of the disorder. Severe bilateral varicose veins are a common problem.

Associated pulmonary complications of EDS include spontaneous pneumothorax, pneumomediastinum, and

Figure 105-9 Maneuvers that may be used to establish the presence of clinically significant joint laxity found in Ehlers-Danlos syndrome. It is not unusual to find extreme laxity of the small joints and less laxity in large joints. Laxity decreases with age, so the dominant nature of most of these syndromes may not be appreciated when examining older family members. (Redrawn and modified from Wynne-Davies R: *Acetabular dysplasia and familial joint laxity: two etiological factors in congenital dislocation of the hip—a review of 589 patients and their families*, J Bone Joint Surg Br 52:704, 1970.)

subpleural blebs.¹⁰⁷ Mitral valve prolapse and tricuspid valve insufficiency may complicate classic EDS, and aortic root dilation has been reported, although the rate of progression is unknown.^{108,109} Skeletal abnormalities include thoracolumbar kyphoscoliosis; a long, giraffe-like neck; downward sloping of the ribs of the upper part of the thorax; and a tendency toward reversal of the normal cervical, thoracic, and lumbar curves. Anterior wedging of thoracic vertebral bodies is occasionally seen.¹¹⁰

Hypermobility Type

The hypermobile type of EDS is a dominantly inherited disorder that manifests as marked joint and spine hypermobility, recurrent joint dislocations, and the typical soft skin that is neither hyperextensible nor velvety. Individuals with EDS type III may have virtually normal skin. Because of the extent of joint laxity affecting large and small joints, these patients experience multiple dislocations and may require surgical repair. The shoulders, patellae, and temporomandibular joints are frequently sites of dislocation. Musculoskeletal pain may mimic that of fibromyalgia syndrome, and patients frequently seek medical attention for symptoms consistent with chronic pain.

One difficulty in this subtype is differentiating it from benign hypermobility syndrome. Benign hypermobility syndrome is used to describe patients with generalized joint laxity, associated musculoskeletal complaints, but normal skin. They do not have the classic stigmata of either EDS or Marfan syndrome. Many of these patients present in their 20s and 30s with rheumatologic symptoms that can pose

problems in diagnosis and treatment. The precise approach and treatment for these patients are unclear.

Structural and Molecular Pathology of the Classic and Hypermobile Types of Ehlers-Danlos Syndrome

Abnormally large, small, or frayed dermal collagen fibrils and disordered elastic fibers have been observed in the classic and hypermobile forms of EDS by electron microscopy.¹¹¹ Type V collagen is a heterotrimeric collagen composed of the products of three genes: COL5A1(V), COL5A2(V), and COL5A3(V). Type V collagen may stabilize type I collagen by co-assembling with that protein. Initially, linkage analysis was used to show that some families with the classic form of EDS (originally types I and II) were linked to COL5A1. Subsequently, it has been established that about 50% of patients with either the classic or hypermobility type of EDS have mutations in COL5A1(V) or COL5A2(V). There seems to be no genotype-phenotype correlation in these disorders, and no mutations have been identified in COL5A3(V). In some cases of EDS classic type, heterozygosity for mutations in COL1A1(I) has been shown.¹¹²

Vascular Type

The vascular type of EDS, an autosomal dominant disorder, is one of the most severe forms of EDS and was formerly referred to as *EDS type IV*. It is associated with arterial rupture, commonly involving iliac, splenic, or renal arteries or the aorta and resulting in either massive hematomas or death.¹¹³ Arterial rupture may lead to stroke or intracompartmental bleeding in a limb. Patients with vascular EDS also are susceptible to rupture of internal viscera and may experience repeated rupture of diverticula on the antimesenteric border of the large bowel. Problems with pregnancy vary from preterm delivery to uterine or vascular rupture, although delivery is uneventful in many instances.¹¹⁴ Typical causes of death in EDS families have included gastrointestinal rupture, peripartum uterine rupture, rupture of the hepatic artery, and vascular ruptures.

In contrast to the other forms of EDS, EDS type IV is not associated with hyperextensibility of large joints, although small joints may be minimally hypermobile. These patients have thin, soft, transparent skin, through which a prominent venous pattern is seen, especially on their chest walls. Their skin is not velvety as in the classic form. Excessive bruisability may occur. Vascular EDS includes, as a subgroup, patients who have been described as acrogyric—having characteristically thin faces, prominent eyes, and extremities that lack subcutaneous fat, giving the appearance of premature aging. Peripheral joint contractures and acro-osteolysis have been described.

Spontaneous hemopneumothorax associated with hemoptysis and mitral valve prolapse occurs frequently. Surgical repair of ruptured vessels or internal viscera is extremely difficult because of friable tissues. Anesthetic and surgical difficulties related to intubation, spontaneous arterial bleeding during surgery, and ligation of vessels that tear under pressure complicate surgical maneuvers. Similarly, arteriography may be dangerous in these individuals. These patients

can be quite difficult to manage. Imaging studies may reveal normal-appearing aorta or other large vessels that rupture shortly after a “normal study.”

Molecular Pathology

Although EDS type IV was clinically recognized as a disorder distinct from the other forms of EDS, the finding that tissues from these individuals were deficient in type III collagen clearly distinguished this as a separate form of EDS. Type III collagen is a homotrimer [1(III)3] found in skin, blood vessels, and the walls of hollow viscera. Heterozygosity for mutations in the gene encoding *COL3A1* leads to EDS vascular type and affects the synthesis and secretion of type III collagen. Various types of mutations have been identified including missense, nonsense, and deletions, and there is no correlation between the clinical phenotype and type III collagen mutation. In this disorder, the biochemical abnormalities include decreased or absent type III collagen or production of an abnormal homotrimer that is retained in the endoplasmic reticulum and, if secreted, contributes to abnormal matrix. Biochemical and mutational analysis for this disorder is available (GeneTests) and should be considered because this is dominantly inherited.

Therapy in Classic, Hypermobility, and Vascular Types of Ehlers-Danlos Syndrome

There are no specific treatments for the classic, hypermobility, and vascular forms of EDS. Supportive therapy is essential, however, for preservation of normal joint function and alleviation of joint pain. Planned exercise programs and muscle strengthening exercises are useful and do much to maintain a positive outlook in these individuals, who may have a poor prognosis if joint stability and articular surfaces are compromised by excessive activity or chronic trauma. Many children and young adults with large joint hypermobility are attracted to activities such as gymnastics and dance, and these activities promote hypermobility and joint damage. The presence of multiple ecchymoses raises concern about a bleeding diathesis, particularly at the time of elective surgery. Although there is no consistent basis for the hemorrhagic tendency in the classic and hyperextensibility forms of EDS, anecdotally, these patients tend to have greater blood losses than expected at surgery. In our center, we discourage pregnancy in patients with the vascular form because the mortality rate is increased.

Arthrochalasia Type

Formerly known as EDS types VIIA and VIIB, the arthrochalasia type of EDS is another autosomal dominant form resulting from mutations that cause faulty processing of type I collagen at the N-terminus. The arthrochalasia type of EDS is characterized by pronounced and generalized joint hypermobility, moderate cutaneous elasticity, moderate bruising, a characteristic round facies with midface hypoplasia, and significant short stature. The skin has a doughy feel and is fragile and hyperelastic. Kyphoscoliosis and muscle hypotonia are frequently present. These patients experience multiple dislocations, particularly involving large joints including the hips, knees, and ankles. These

dislocations manifest in the newborn period, especially hip and ankle dislocations. Patients frequently need orthopedic surgery for joint dislocation, and their tissues are highly friable, which complicates orthopedic procedures.

Molecular Pathology

The two disorders EDS types VIIA and VIIB, now termed *arthrochalasia type*, result from mutations involving the N-terminal propeptide cleavage site of type I collagen.¹¹⁵⁻¹¹⁷ The arthrochalasia type of EDS has provided insight into the process of normal type I collagen fiber formation. The initial observation was of an accumulation of unprocessed procollagen within the dermis of affected individuals. With subsequent recognition that procollagen had N-terminal and C-terminal extension propeptides, and that separate enzymes were responsible for their removal, the syndrome became more sharply defined as an accumulation of procollagen with the N-terminal peptides still attached (pN collagen).¹⁰⁰ Of the two distinctly different genetic abnormalities resulting in procollagen accumulation, the more frequent form is the mutational resistance of a procollagen cleavage site to the action of the N-terminal procollagen peptidase. The resistance results from an amino acid substitution or deletion in the proCOL1A1 (EDS type VIIA) or pro2COL2A1 (EDS type VIIB) chain, leading to a portion of the collagen chains containing an abnormal N-terminal extension; this results from mutations in *COL1A1* or *COL1A2* in exon 6 of the molecule, which alters the proteinase cleavage site. Individuals with mutations in exon 6 of *COL1A1* are more severely affected than individuals with similar mutations in *COL1A2*.¹¹⁶

Dermatosparaxis Type

The dermatosparaxis type of EDS was formerly known as *EDS type VIIC* and is an autosomal recessive form of EDS. In this type, the skin is extremely fragile, soft, and doughy with easy bruising. The phenotype includes blue sclerae, marked joint hypermobility, micrognathia, large umbilical hernia, epiphyseal delay, and mild hirsutism.¹¹⁷ The dermatosparaxis type results from a deficiency of the procollagen N-propeptidase, in contrast to the arthrochalasia form, which involves the enzyme cleavage site, and individuals have been identified who are homozygous for mutations in the gene.¹⁰³ This defect is homologous to the dermatosparaxis defect in sheep and cattle.¹¹⁸

Kyphoscoliosis Type

The kyphoscoliosis type of EDS, formerly known as *EDS type VI*, is inherited as an autosomal recessive disease. The findings in this disorder include severe kyphoscoliosis noted at birth, recurrent joint dislocations, hyperextensible skin and joints, poor tone, and reduced muscle mass.¹¹⁹ The skin is grossly abnormal and has been described as pale, translucent, and velvety; on trauma, the skin shows gaping wounds that heal poorly. One difference in this form of EDS is that there is significant ocular involvement. Affected individuals have microcornea, retinal detachment, and glaucoma leading to blindness in some individuals. In addition, patients with severe kyphoscoliosis may develop respiratory

and cardiac compromise and ultimately cardiorespiratory failure.

Molecular Pathology

The kyphoscoliosis type of EDS results from lysyl hydroxylase deficiency.¹¹⁹ A variety of mutations within the lysyl hydroxylase gene have been defined and include premature stop codons, amino acid substitutions, internal deletions, and compound heterozygotes.¹¹⁹ Defective lysyl hydroxylase impairs the conversion of lysyl residues to hydroxylysine on procollagen peptides. The consequence of deficient hydroxylysine content of collagen is the effect it has on cross-linking, which helps stabilize the mature collagen molecule.

Other Ehlers-Danlos Syndrome Types

Numerous other rare forms of EDS have some overlap with other disorders or have been reported only in a small cohort of individuals, and these are not discussed in this chapter.

MARFAN SYNDROME

One of the most common inherited disorders of connective tissue, Marfan syndrome is an autosomal dominant disorder with a reported incidence of 1 in 10,000 to 20,000 individuals.¹²⁰ Clinical presentations range from the severe infantile form to individuals who are only mildly affected. Although the most impressive findings in Marfan syndrome are relative to the musculoskeletal, cardiac, and ocular findings, affected individuals also have pulmonary, neurologic, and psychological complications. Marfan syndrome also has become one of the few genetic disorders for which there has been advocacy for treatment to slow the progression of the disease, and physicians need to recognize the phenotype because many affected individuals present with life-threatening emergencies.

Clinical Features

Marfan syndrome can be difficult to diagnose in some individuals and families, and it has been recognized that it has also been overdiagnosed. Stringent criteria for this diagnosis were proposed in 1996.¹²⁰ The 1996 criteria rely on the recognition of “major” and “minor” clinical manifestations involving the skeletal, cardiovascular, dura, and ocular systems (excellent review in *GeneReviews*, Marfan syndrome). Major criteria include four of eight typical skeletal manifestations, ectopia lentis, aortic root dilation involving the sinuses of Valsalva or aortic dissection, and lumbosacral dural ectasia by computed tomography or MRI. Major criteria for establishing the diagnosis in a family member include having a parent, child, or sibling who meets major criteria independently, and the presence of a *fibrillin-1* mutation known to cause the syndrome identified in a familial Marfan syndrome patient.

Establishing the diagnosis unequivocally in the absence of a family history requires a major manifestation from two systems and involvement of a third system. If a mutation known to cause Marfan syndrome is identified, the diagnosis

requires one major criterion and involvement of a second organ system. The reason is that there is a great deal of intrafamilial variability in this disorder, and there are individuals who harbor heterozygosity for mutations but do not meet criteria for Marfan syndrome and may have different prognoses.¹²¹ Similar to other connective tissue disorders, there is wide variability in phenotypic expression.

Aortic disease leading to the formation of aneurysmal dilation and dissection is the main cause of morbidity and mortality in Marfan syndrome.¹²² Dilation of the aorta is found in 50% of children and progresses over time. Echocardiography shows that 60% to 80% of adult patients have dilation of the aortic root that may involve other segments of the thoracic aorta, the abdominal aorta, or even the carotid and intracranial arteries. Dissection usually begins above the coronary ostia and extends the entire length of the aorta. Of Marfan syndrome patients, 60% to 70% have mitral valve prolapse with regurgitation. Heart failure and myocardial infarction may complicate the course of Marfan syndrome patients. Pregnant women are at particular risk for aortic dissection, particularly women who already have aortic root dilation, and this should be taken into consideration when treating a woman of reproductive age with Marfan syndrome.¹²³

Arachnodactyly occurs in 90% of patients. Following are techniques that aid in determining arachnodactyly (Figure 105-10):

1. The thumb: The Steinberg test is positive when the thumb, enclosed in the clenched fist, extends beyond the hypothenar border.
2. The wrist: The Walker-Murdoch sign is positive when there is overlap of the thumb and fifth digit as they encircle the opposite wrist.
3. The metacarpal: The metacarpal index is done by radiographic determination and is the mean value of the lengths divided by the midpoint widths of the second, third, and fourth metacarpals. In normal subjects, the metacarpal index ranges from 5.4 to 7.9, whereas this range is 8.4 to 10.4 in patients with Marfan syndrome.

Thoracic kyphosis may be associated with reduced lung capacity and residual volume that may lead to pulmonary insufficiency. Dural ectasia, which may occur in 40% of patients, results from enlargement of the spinal canal owing to progressive ectasia of the dura and neural foramina and erosion of vertebral bone; this usually involves the lower spine.¹²⁴ Diminished bone mineral density has been reported in several patients with Marfan syndrome.¹²⁵ Ectopia lentis occurs in 50% to 80% of patients with Marfan syndrome. Subluxation of the lens is usually bilateral and appears by age 5 years. Although the lens is typically displaced upward, displacement into any quadrant may occur. Visual acuity is diminished in many patients because of lens subluxation or secondary acute glaucoma. Secondary myopia, retinal detachment, and iritis with loss of vision contribute to most of the ocular-related morbidity.¹²⁶

Marfan syndrome patients have been found to develop large epidural venous plexuses in the lumbar and cervical regions, a major diagnostic criterion for the syndrome. These engorged venous plexuses, which are visualized by MRI myelography, have been associated with the syndrome of spontaneous intracranial hypotension, which is also

Figure 105-10 Marfan syndrome. The Steinberg test (thumb) and the Walker-Murdoch test (wrist) show arachnodactyly.

associated with dural tears. Clinical signs are severe headache, back and leg pain, radiculopathies, and incontinence secondary to cerebral displacement.¹²⁷ Spinal abnormalities in Marfan syndrome include increased interpedicle distance of nonrotated vertebrae, vertebral inversion (flattening of the normal kyphosis at the dorsal level and kyphosis or disappearance of the physiologic lordosis at the lumbar level), and vertebral dysplasia (dolichospondylic, elongated vertebral bodies with increased concavity). Scoliosis constitutes one of the major management problems in Marfan syndrome. In one series, the average age of onset was 10.5 years (range, 3 to 15 years), with rapid progression during adolescence.¹²⁸ If mechanical bracing or physical therapy fails to halt progression, spinal fusion should be considered, particularly when the curvature exceeds 45 to 50 degrees.

Differential Diagnosis: Homocystinuria

Homocystinuria, which shares several skeletal and ocular features with Marfan syndrome, is the prime diagnostic consideration. Homocystinuria is an autosomal recessive disease. The characteristic features of this metabolic disorder of sulfur metabolism are marfanoid phenotype with joint laxity, scoliosis, lens dislocation, early-onset osteoporosis, vascular thrombosis affecting arteries and veins owing to increased clotting activity and the cytotoxic effect of homocysteine on vascular endothelial cells, and mild mental retardation.¹²⁹

Cystathionine β -synthase deficiency is the most common cause of homocystinuria.¹³⁰ Affected individuals have elevated levels of homocystine and methionine, whereas cystathionine and cysteine levels in blood are decreased. This disorder is differentiated from Marfan syndrome

because the direction of ectopia lentis is different than in Marfan syndrome, and there is no progressive aortic root dilation.

Molecular Biology of Marfan Syndrome

Fibrillin-1 protein is an important component of elastic and nonelastic connective tissues throughout the body.¹³¹ It is the main protein of a group of connective tissue microfibrils that are essential for normal elastic fibrillogenesis. In nonelastic tissues, the fibrillin-1-containing microfibril functions as an anchoring fiber. *FBN-1* is a large gene (65 exons) located at chromosome 15q21.1.

Since the first report of an *FBN-1* mutation in Marfan syndrome in 1991, more than 500 different *FBN-1* mutations have been described in Marfan syndrome and related disorders.¹³² *FBN-1* mutations occur across a wide range of milder phenotypes that overlap the classic Marfan phenotype including dominantly inherited ectopia lentis, Shprintzen-Goldberg syndrome, and familial or isolated forms of aortic aneurysms.¹³³ Most of these are private mutations (occur genetically independent with no “hot spot” in the molecule). The one exception is the rare infantile Marfan syndrome mutations that cluster between exons 24 and 26 and exon 32. Heterozygosity for missense, frame-shifts, deletions and insertions, splice site alterations, and nonsense mutations all have been seen.¹ Robinson and colleagues¹³³ stated that at least 337 mainly unique mutations in the *FBN-1* gene had been reported in Marfan syndrome up to that time. The clinical presentation of the fibrillinopathies caused by *FBN-1* mutations ranged from isolated ectopia lentis to neonatal Marfan syndrome, which generally leads to death within the first 2 years of life.

Treatment

In 1972, the life span of untreated patients with classic Marfan syndrome was about 32 years. The early mortality in Marfan syndrome results primarily from complications associated with aortic dilation. This symmetric dilation of the sinuses of Valsalva is progressive throughout life and is often detectable in infancy. In the early 1970s, there was discussion on attempting to reduce the risk of aortic dissection in patients with Marfan syndrome. Shores and colleagues¹³⁴ reported on a 10-year open-label trial of propranolol in 70 patients with Marfan syndrome. When compared with the control group, the treated individuals had a significantly slower rate of dilation of the aortic root, improved survival, and fewer treated patients reaching a clinical endpoint (death, congestive heart failure, aortic regurgitation, aortic dissection, or cardiovascular surgery).

More recent data generated from a mouse model of Marfan syndrome suggest excessive signaling by the transforming growth factor transforming growth factor (TGF)- β family of cytokines.¹³⁵ There is evidence that aortic aneurysm in the mouse model of Marfan syndrome is associated with increased TGF- β signaling and TGF- β antagonists such as TGF- β -neutralizing antibody or the angiotensin II type 1 receptor blocker, losartan. In this mouse model, losartan (angiotensin II type 1 blockade) fully corrected the abnormalities in the aortic wall. There was some evidence that alveolar septation, which contributes to pulmonary problems in Marfan syndrome, was partially reversed with losartan treatment. Because this drug is in clinical use for hypertension, it could merit further investigation as a preventive treatment in Marfan syndrome. Clinical trials are now under way testing the use of losartan in Marfan syndrome and many individuals with Marfan syndrome are using losartan outside of clinical trials.

Electrocardiogram monitoring is done yearly until the aortic root diameter exceeds 45 mm, at which time monitoring is done every 6 months. Elective repair of aortic root disease before enlargement to 6 cm has occurred is preferable to emergency repair required for marked dilation or dissection. Surgical intervention is considered when the aortic root diameter approaches twice the upper limit of normal for body surface area, or the absolute measurement exceeds 50 to 55 mm. Total aortic root replacement with a composite valve graft (Bentall procedure) and coronary artery implantation have become the surgical procedures of choice and are associated with an 81% 10-year survival rate and a 75% 20-year survival rate.^{136,137} Mitral valve replacement and coronary artery implantation may be accomplished during the same procedure. Most importantly, repeated trials have shown that patients who undergo elective repair, as opposed to emergent repair, do substantially better.

Correction of scoliosis may be attempted with bracing; however, surgical repair should be considered when the curve exceeds 40 degrees. Progressive scoliosis in Marfan syndrome may require fixation with rods, and complications of joint laxity may require orthopedic correction. Arthropathy associated with excessive joint mobility may require orthopedic intervention. Dislocated lenses should not be removed surgically, unless more conventional means of correcting vision are ineffective.

LOEYS-DIETZ SYNDROME

In 2005, Loeys and colleagues¹³⁸ described individuals with a previously undescribed autosomal dominant aortic aneurysm syndrome. This disorder, now referred to as *Loeys-Dietz syndrome*, also is characterized by hypertelorism, bifid uvula or cleft palate or both, and generalized arterial tortuosity with ascending aortic aneurysm and dissection. Other abnormal findings include craniosynostosis, structural brain abnormalities, mental retardation, congenital heart disease, and aneurysms with dissection throughout the arterial tree.

Some individuals with Loeys-Dietz syndrome had a clinical phenotype that overlapped with Marfan syndrome, but none met diagnostic criteria set forth in 1996.¹³⁸ Although Marfan syndrome is associated with progressive arterial disease, in Loeys-Dietz syndrome the aneurysms tended to be particularly aggressive and rupture at an earlier stage and size than seen in Marfan syndrome. Heterozygosity for mutations in *TGFBR1* and *TGFBR* has been identified.¹³⁸ From a management perspective, it is important to recognize these individuals because they are managed more aggressively than patients with Marfan syndrome. Aortic aneurysms are corrected at smaller sizes (4 cm), and complaints such as abdominal pain and headache should be thoroughly investigated because they may be associated with aneurysms.

CONGENITAL CONTRACTURAL ARACHNODACTYLY

Congenital contractural arachnodactyly is an autosomal dominant condition that includes tall stature, arachnodactyly, dolichostenomelia, and multiple contractures involving large joints.¹³⁹ There is a characteristic “crumpled ear” deformity as a result of a flattened helix with partial obliteration of the concha. Marked deformity of the chest cage also occurs, and scoliosis may be progressive and severe. For unknown reasons, the contractures tend to become less severe with age. Radiographically, osteopenia can be seen. The ocular and typical cardiac lesions of classic Marfan syndrome are absent. This disorder results from heterozygosity for mutation in *fibrillin-2* (*FNB-2*).¹⁴⁰ There are many other extremely rare disorders of connective tissue, especially with profound effects on the skin including the group of disorders termed *cutis laxa* and *pseudoxanthoma elasticum*.^{141,142}

SUMMARY

Heritable disorders of connective tissues are a heterogeneous group of disorders characterized by abnormalities in skeletal tissues including cartilage, bone, tendon, ligament, muscle, and skin. The clinical spectrum ranges from extreme short stature to excessively tall individuals, and the types of altered genes span all of the numerous gene families and pathways. Affected individuals usually need medical attention their entire lives and have been victims of appearing different because they cannot mask their abnormalities. Understanding and appreciation for the unique set of medical issues in each disorder would improve these individuals' quality of life and their life span.

Etiology and Pathogenesis of Juvenile Idiopathic Arthritis

LUCY R. WEDDERBURN • KIRAN NISTALA

KEY POINTS

Juvenile idiopathic arthritis (JIA) is a group of conditions with distinct clinical phenotypes and likely differing underlying pathogenic mechanisms.

The heterogeneity of JIA at pathologic and immunologic levels is informative in driving the understanding of these diseases.

An increasing number of genes, outside of the major histocompatibility complex (MHC) locus, have been linked to JIA, but taken together these still account for relatively little of the heritability of JIA.

In JIA, there is evidence to support abnormalities in both innate and adaptive immune systems. Successful treatments may require targeting of multiple cytokine pathways in a single patient.

Strong links with MHC loci and the presence of inflammatory T cells within the inflamed synovium support a role for adaptive immunity in the pathogenesis of JIA.

Systemic arthritis has an immune profile distinct from other types of JIA. Inflammatory mediators of the innate immune system including interleukin (IL)-1 β , IL-6, and myeloid related protein play a major role in disease pathogenesis.

Juvenile idiopathic arthritis (JIA) comprises a heterogeneous group of diseases that lead to a final common pathway, namely thickening and inflammation of the joint lining with characteristic onset in children. Infiltrating inflammatory cells interact with each other and resident synovial fibroblasts, promoting a chronic inflammatory process in the synovial membrane and secreted synovial fluid (Figure 106-1). In this chapter, we discuss the genetic factors that predispose to JIA and the abnormalities that underlie synovial and systemic inflammation. In addition to the established association between the major histocompatibility complex (MHC) loci and JIA, more recent studies have detected links to genes that regulate cellular activation or cytokine responses.¹ The fact that immune-related genes make up the major risk alleles in JIA strongly supports the concept of JIA as a disease of disordered immunity. Highly

activated T cells, monocytes, and neutrophils are attracted to joint and secrete mediators that perpetuate inflammation and also attenuate immune regulation. The relative importance of individual cytokines varies between disease subtypes. Results from therapeutic trials support a role for tumor necrosis factor (TNF) in the pathology of polyarthritides forms of JIA and for interleukin (IL)-1 β and IL-6 in systemic JIA (sJIA) (Table 106-1). The past decade has seen a step change in the quality of treatments in JIA. To build on this success, researchers need to be able to interrogate the vast array of biologic data that is emerging in the field of JIA and translate this knowledge into novel therapies and a more tailored treatment approach for our patients.

The term *juvenile idiopathic arthritis* refers to a group of conditions, defined under the International League of Associations for Rheumatology (ILAR) classification as conditions starting before the sixteenth birthday that are characterized by arthritis of at least one joint that persists for 6 weeks or more, as a common feature.² Although this classification has proven highly valuable for both clinical and basic research and enables more precisely defined subgroups and comparison of data from different studies, it does not encompass all aspects of the heterogeneity of childhood arthritis (e.g., use of the classification criteria by strict exclusion rules may lead to up to 30% of cases being designated as “unclassified”). In addition, certain common features may occur across several subtypes (e.g., factors associated with risk of autoimmune uveitis of JIA include positivity of the antinuclear antibody [ANA], early age at onset, and female sex). Girls with young-age onset of arthritis and ANA positivity represent a group of patients who have been proposed to represent a relatively homogeneous group, yet they currently fall into several subtypes within the ILAR classification. Similarly, genes and immunologic processes that influence the likelihood of mild oligoarthritis to extend to more severe arthritis may well overlap with etiopathologic factors involved in polyarticular JIA.^{3,4} Thus in the future a full molecular and genetic analysis of the heterogeneity of childhood arthritis may permit the development of a more mechanism-driven classification, which could help inform

Figure 106-1 Sections of synovium from the knee of a child with oligoarticular juvenile idiopathic arthritis showing intense inflammatory infiltrate and highly vascular hypertrophied tissue. **A**, Stained for CD3 (surface protein on T lymphocytes) (magnification, $\times 100$). **B**, Stained for intracellular adhesion molecule 1, which is expressed on the endothelium and a proportion of the infiltrating cells (magnification, $\times 200$). **C**, Stained for CD34, expressed on vascular endothelium (and hematopoietic stem cells) (magnification, $\times 100$).

on likely disease course, complications, or response to treatment.

Both genetic and environmental factors, as well as the manifestations of their interactions through inflammatory and immunologic mechanisms, are clearly implicated in the

pathogenesis of JIA. Recent advances in the understanding of some clinical subtypes, most notably sJIA, have led to recognition of specific and distinct features and novel treatment options. However, it is also increasingly clear that some underlying genetic risk associations and immune

Table 106-1 Summary of Cytokines and Inflammatory Mediators Implicated in Juvenile Idiopathic Arthritis

Cytokine/Mediator	Cell	Pathology
TNF	Monocytes, T, B cells, PMN, mast cells, fibroblasts	Activates monocytes and neutrophils Damages cartilage \uparrow Endothelial cell adhesion molecules Inhibits regulatory T cells
IL-1 β	Monocytes, B cells, fibroblasts	Activates osteoclasts (bone damage) Fibroblast cytokine, chemokine release \uparrow Endothelial cell adhesion molecules
IL-17	T cells (Th17), mast cells	Chemokine release (recruit PMN) Cartilage damage Activates osteoclasts
IL-6	Monocytes, fibroblasts, B cells	Synergizes with TNF and IL-1 β B cell activation Inhibits regulatory T cells Growth retardation
IFN- γ	T cells (CD4 $^{+}$ Th1, CD8 $^{+}$, NK cells)	Acute-phase response and anemia Activates monocytes \uparrow Endothelial cell adhesion molecules
MRP 8/14	Monocytes, PMN	May assist recruitment of Th17 cells Activates monocytes Promotes pathologic CD8 $^{+}$ T cells Secretion of IL-1 β \uparrow Endothelial cell adhesion molecules

IFN- γ , interferon-gamma; IL, interleukin; MRP, myeloid related protein; NK, natural killer; PMN, polymorphonuclear neutrophil; TNF, tumor necrosis factor.

abnormalities may have effects across several types of childhood arthritis and indeed across many forms of autoimmune disease.

HISTOLOGIC FEATURES OF JUVENILE IDIOPATHIC ARTHRITIS INFLAMED SYNOVIUM

The pathologic hallmark of juvenile idiopathic arthritis is the inflamed synovium. Histology of this tissue shows thickened synovium that is highly vascular and shows marked hyperplasia of synoviocytes in the lining layer, as well as a dense infiltrate of inflammatory cells, comprising T cells, macrophages, dendritic cells, and in some cases B cells and natural killer (NK) cells^{5,6} (see Figure 106-1). The hypertrophied synovial layer is highly vascular, with endothelium expressing markers of activation such as human leukocyte antigen (HLA)-DR and intracellular adhesion molecule 1 (ICAM-1). The vascularity is likely related to the increased production of proangiogenic factors such as vascular endothelial growth factor (VEGF), osteopontin, and the angiogenic chemokines,⁷⁻⁹ while recruitment of this inflammatory infiltrate is likely mediated by multiple chemokines shown to be increased in JIA including CCL5, CXCL10, CCL20, IL-8, and MCP-1 among others.^{10,11} The proteolytic enzymes matrix metalloproteinases MMP-1 and MMP-3 are abundantly expressed in synovial lining, and their levels correlate with degree of infiltration, in particular by myeloid CD68⁺ cells.¹¹ The T cells that infiltrate the inflamed synovium, like those in the excess synovial fluid, are highly activated memory cells¹²⁻¹⁴ of both CD4 and CD8 populations.¹⁵⁻¹⁷

GENETICS OF JUVENILE IDIOPATHIC ARTHRITIS

KEY POINTS

There is strong evidence for a genetic component to the etiology of JIA.

The strongest genetic associations of JIA are with genes of the MHC.

Specific MHC class I alleles are associated with enthesitis-related arthritis (ERA).

Distinct MHC class II alleles are associated with oligoarthritis and polyarthritis subtypes.

Several genes that alter the threshold of T cell activation, or relate to cytokines and their receptors, are linked with JIA.

There is strong evidence for a genetic component to the etiology of the JIA diseases. Twin studies have shown concordance rates in monozygotic twins of between 20% and 40%.¹⁸ A study of 164 affected sibling pairs (ASPs) with JIA showed a 70% concordance for gender, 73% for age at disease onset, and 66% for disease course.¹⁹ Estimates suggest that the recurrence risk for siblings of a proband with JIA are between 15 and 30 times that of the general pediatric population, a figure that is as high as for insulin-dependent diabetes mellitus (IDDM) or multiple sclerosis.²⁰ In addition, first-degree relatives of children with JIA have a higher

rate of other autoimmune disease than controls.²¹ Despite this evidence, families of multiple affected siblings are still relatively rare. One caveat in comparing early studies is that some were performed using the American College of Rheumatology (ACR) classification criteria (at that time called *juvenile rheumatoid arthritis*), so they may not be directly comparable with studies that have used the current ILAR classification of JIA. However, there is now a growing body of data that has been analyzed using the ILAR criteria, making comparisons feasible.

Genetic influences on JIA susceptibility and phenotype are polygenic, such that JIA is thought of as a complex genetic trait.²⁰ Although some studies have analyzed all forms of JIA together, the heterogeneity of childhood arthritis would lead to the prediction of different genetic risk associations for different disease phenotypes, and this has been confirmed in recent adequately powered studies. The unique features of different subtypes of JIA mean that it is perhaps unsurprising that there are also genetic associations with specific subtypes.

The strongest genetic associations with JIA are of genes that lie within the MHC, or HLA; these were the first to be documented as associated with childhood arthritis.²² The MHC region, located on chromosome 6 of the human genome, includes more than 200 genes, many of which are central to functions of the immune system. Numerous associations between HLA genes and JIA have been reported, and these involve many different populations (reviewed by Prahalad and Glass¹). The best characterized associations are with genes of the so-called MHC class I and class II loci, genes that code for heterodimeric proteins that present peptide antigen to the specific antigen receptor of T cells (the TCR).

Class I loci include HLA-A, HLA-B, and HLA-C, of which the earliest report was of the association between HLA-B27 and the form of JIA known as *enthesitis-related arthritis* (ERA), which includes children whose disease has parallels with adult ankylosing spondylitis (see Chapters 74 and 75). The HLA-A2 allele HLA-A*0201 is increased in several types of JIA, especially oligoarthritis and children with early-age onset.^{23,24} A recent study has also implicated HLA-C*0202 in association with persistent oligoarticular JIA.²⁵

Multiple studies have revealed associations of class II MHC loci (HLA-DR, HLA-DP, and HLA-DQ) with JIA, of which the strongest are DRB1*0801 and 11 with oligoarticular JIA, as well as DRB1*1301, in particular in ANA-positive cases.²⁶ Because of inheritance of genes in the MHC region together in so-called haplotypes due to linkage disequilibrium (LD), observed associations may in fact be due to genes within the haplotype, distinct from the locus first implicated. Several haplotypes across the MHC confer an increased risk for all types of JIA such as DRB1*08-DQA1*0401-DQB1*0402, which confers an odds ratio of 6.1 and 10.3 for persistent and extended oligoarticular JIA, respectively. Frequency of the DRB1*1301-DQA1*01-DQB1*06 haplotype distinguishes persistent from extended oligoarticular JIA, whereas DRB1*0801 and DRB1*1401 are associated with polyarticular JIA.²⁶ Together, these effects may be large: In one study the presence of the combination of the HLA-DRB1*0801, HLA-DRB1*1101, and DPB1*0201 alleles conferred a relative risk of 236.²⁷ Some

associations closely mirror those of the corresponding adult disease such as the strong association of the HLA-B27 allele with spondyloarthropathy and the HLA-DRB1*0401 with rheumatoid factor (RF)-positive polyarticular JIA. Although sJIA shows less strong associations with HLA alleles, even in this subtype, specific haplotypes (such as DRB1*11-DQA1*05-DQB1*03) are increased compared with control subjects. A recent study that used fine allele-specific typing across eight HLA loci in a large cohort and analysis by haplotype has confirmed that within class II loci, HLA-DR is the driving association, rather than HLA-DP.²⁵ Remarkably, some HLA allele/JIA subtype associations show age-specific effects, in that they confer risk over a specific age range only.²⁴ Another recent study confirmed both age- and gender-specific effects.²⁵ Thus, for example, in polyarticular JIA the HLA-DRB1*0801 allele has risk effect in those whose arthritis starts after the age of 6, whereas in younger-onset polyarticular JIA the risk alleles are more closely related to those of patients with oligoarticular JIA, HLAB1*1103/1104.²⁵ In addition to these risk alleles, some alleles, notably DRB1*0401, *0701 and *1501, are consistently reduced in frequency in JIA cases compared with controls, suggesting a protective effect, for some or even all subtypes. These associations between genes that code for proteins whose central function is the presentation of antigenic peptides to T cells implicate a T cell-driven process in at least part of the etiopathogenesis of JIA.

In addition to the genes coding for MHC proteins, a large number of other candidate genes (now totaling more than 100) have been the focus in different studies of JIA.²⁸ Inflammatory cytokines have been an important target for drug development in JIA over the past decade, and similarly their gene polymorphisms have been a key area of scrutiny. Genes studied have included cytokine and chemokine genes such as IL-1, IL-6, TNF, MIF, and IL-10; their receptors (including IL-1R, IL-2RA, and CCR5); and key signaling molecules including CTLA4 and PTPN22. However, only a few of these loci have been independently validated: PTPN22, MIF, SLC11A6, WISP3, TNF,^{1,29} and in a recent meta-analysis, CCR5.³⁰

Genetic association at the TNF locus is complex to study given the position of the TNF gene within the MHC, but some data suggest that several HLA-independent TNF haplotypes are significantly associated with JIA, although the functional consequences of these alleles are not yet clear.³¹ The hypothesis suggesting a link between sJIA and IL-6 was proposed many years ago because several clinical features in sJIA resembled the phenotype of IL-6 overexpression (e.g., fevers, stunted growth, anemia).^{32,33} A polymorphism (−174G/C) in the regulatory region of the IL-6 gene alters transcription of IL-6 in response to IL-1 and LPS; sJIA patients have significantly lower frequency of the protective CC genotype,³⁴ and the IL-6 −174G allele has been confirmed as a susceptibility gene for sJIA.³⁵ Macrophage inhibitory factor (MIF) gene is associated with JIA.³⁶ This polymorphism (MIF −173*C) results in higher MIF production in the serum and synovium of JIA patients and has been suggested to be predictive of outcome of intra-articular steroid injections in sJIA.³⁷

The apparently conflicting studies on several of these candidate gene loci reflect two problems that have hindered progress: the heterogeneity of JIA, which means that

combining all JIA into one study may lead to loss of detection of effects specific for a subtype, and opposing this, the difficulty of reaching adequate power for genetic studies, if stratification by subtype is preferred. Recently, new insights have come from the application of new knowledge from other diseases to the understanding of JIA genetics. Thus the highly successful Wellcome Trust case control Consortium performed genome-wide association studies in seven major common diseases including rheumatoid arthritis (RA).³⁸ Extrapolation of new loci implicated in RA to JIA has been fruitful and has suggested that other key loci that show association with JIA are IL-2/IL-21 and IL-2RA, the α chain of the IL-2 receptor, also known as CD25.^{39,40} A recent study focused on specific subtypes of JIA and comparison with their adult disease counterparts. The genetic loci IL-23R and endoplasmic reticulum (ER) aminopeptidase-1 (ERAP1) have been identified as carrying risk associations with ankylosing spondylitis (AS) and psoriatic arthritis in adults.⁴¹ Genotyping of these genes in a large cohort of JIA cases has shown associations of both with the ERA subtype of JIA but no association with JIA as a whole, again emphasizing subtype-specific genetic features and likely pathogenesis.⁴² ERAP1 is of particular interest given its functional role in trimming of peptides within the ER, for presentation of peptide on, and folding of, MHC class I molecules, and given the strong evidence for MHC class I folding abnormalities in patients with the HLA-B27 risk alleles (HLA-B*2705 and *2702 among others⁴¹); see also section on enthesitis-related arthritis (and Chapter 74). ERAP1 is also thought to have a role in trimming of cytokine receptors at the cell surface. IL-23 is of great functional interest because of the central role of IL-23 in the Th17 pathways, as well as the demonstration that Th17 cells may play a role in both JIA and adult AS/psoriatic arthritis.

New insights into the pathogenesis of childhood arthritis are eagerly awaited from large international efforts to perform genome-wide association studies (GWASs) in JIA, of which several are in progress, some targeting specific subtypes or specific research questions such as response to medication.

ADAPTIVE IMMUNE SYSTEM

KEY POINTS

Effector T cells secreting proinflammatory cytokines are enriched in the joint membrane and synovial fluid.

T cells with a regulatory phenotype have been detected within the joints of JIA patients and are enriched in persistent oligoarthritis patients.

A B cell gene expression signature has been detected in the peripheral blood of patients with early-age onset of JIA.

T Cells

The strong association of many JIA subtypes with genetic variants at HLA loci, as well as the central role of HLA proteins in presenting peptide antigens to T cells for recognition, which is central to T cell function, led to intense investigation of the role of T cells in the pathology of JIA. Highly activated memory T cells make up a significant proportion of the inflammatory infiltrate in JIA and express an

“oligoclonal” or restricted set of T cell receptors (TCRs).^{14,16,17} Specific T cell clones can be long-lived and are detectable in different inflamed joints.¹⁷ Nevertheless, it is still unclear whether these clones represent autoreactive T cells specific for an “arthritogenic” epitope, akin to islet cell antigens in type I diabetes. Although immune activation leads to tissue damage in JIA, the role of self-antigen recognition in this process remains unclear. However, the association of JIA with genetic loci that influence the threshold of T cell activation such as PTPN22, as well as those central to recognition of antigen by T cells, supports the concept of JIA as a disease of dysregulated adaptive immunity.

Early work examining animal models of arthritis led to the hypothesis that cells of the T helper 1 (Th1) lineage, secreting interferon- γ (IFN- γ), were central to pathogenesis. Th1 cells are recruited to the joint by high levels of chemokines CCL5, macrophage inflammatory protein (MIP)-1 α , and IP-10⁴³ and make up the majority of T cells in the JIA joint.¹² However, in both mouse models of arthritis and early adult clinical trials, blocking IFN- γ has offered little clinical benefit, which suggests that other players may be important to pathogenicity. TNF, the prototypic inflammatory cytokine in arthritis, is secreted by T cells and macrophages within the joint and is detectable within inflamed synovial tissue,⁴⁴ and to a lesser extent in synovial fluid.⁴⁵ The success of TNF blockade in polyarthritis and extended oligoarthritis subtypes implicates TNF in JIA pathology.⁴⁶ Still, up to a third of patients fail to respond adequately or relapse on anti-TNF therapy and a recently discovered T cell population, “Th17” secreting IL-17 and IL-22, may account for this recalcitrant disease.⁴⁷ IL-17 causes significant bony and cartilage damage in the joint by promoting neutrophil influx via the secretion of IL-8 and synergizing with IL-1 β and TNF to drive metalloproteinase secretion and osteoclast activation.⁴⁸ Th17 cells are enriched in the joints of JIA patients, and Th17 numbers correlate with the severity of disease course in oligoarthritis.¹¹ Recent evidence suggests that a significant proportion of the inflammatory T cells in the joint have a Th17 ancestry, raising the hope that Th17 blockade will be an effective treatment in some subtypes of JIA.⁴⁹

In addition to proinflammatory processes, there is strong evidence for ongoing immune regulation in JIA. Children with persistent oligoarticular JIA have high numbers of a regulatory subset of T cells (Treg) within the joint that express CD25 and Foxp3, and the number of Tregs is significantly higher in the children with persistent oligoarticular JIA than those with the more severe extended oligoarticular disease.^{50,51} In addition, T cells specific for the conserved self-antigen heat shock proteins (HSPs) play a similar regulatory role.⁵² Although synovial Treg suppress effector T cell functions *in vitro*, inflammatory cytokines such as IL-6 and TNF, present in the arthritic joint,^{10,53} may attenuate Treg function *in vivo*. Treatment strategies that expand Treg numbers and augment function are currently under investigation.^{54,56}

Antigen-Presenting Cells

Dendritic cells are specialized antigen-presenting cells (APCs) that activate T cells, as well as promote the differentiation of effector T cell functions. Comparatively

little is known about their role in JIA. In the inflamed joint, myeloid dendritic cells (mDCs) are localized to the synovial lining layer, whereas interferon- α -secreting plasmacytoid dendritic cells (pDCs) are in T and B cell-rich aggregates.⁴⁵ Both subsets are found in high numbers within synovial fluid when compared with peripheral blood. Synovial mDCs express high levels of co-stimulatory molecules including CD80, CD86, and RANK,^{57,58} which augment T cell activation and lead to the secretion of proinflammatory cytokines and chemokines. A triggering receptor expressed on myeloid cells (Trem-1) may play a role in activating mDCs in response to local hypoxia.⁵⁹ In contrast to mDCs, some studies suggest that synovial pDCs may provide a regulatory function. pDCs within the joint also do express markers of activation⁶⁰ but secrete high levels of Granzyme B, which limits T cell proliferation.⁶¹

B Cells

There has been a renewed interest in B cell effector function in adult arthritis following the efficacy of the anti-CD20 agent, rituximab, in RA. In JIA, the exact role of B cells as effector or regulatory players is still unclear. B cell-derived autoantibodies, antinuclear antibodies (ANAs), RF, and anticitrullinated protein antibodies (ACPAs) are common in some JIA subtypes, but none are considered to be directly pathogenic (see Chapter 107). Interestingly, patients that are ANA positive are more likely to have T-B cell aggregates in their synovial membrane, suggesting a link between lymphoid neogenesis and autoantibody production.⁶² Although lymphoid aggregates are seen in JIA synovium, mature germinal centers are rare when compared with RA.⁶³ Total B cell numbers do not vary between JIA patients and healthy controls, but oligoarthritis patients have higher numbers of transitional type B cells in the synovial fluid exudate (CD38^{high}, CD24^{high}) in peripheral blood than controls.⁶³ Patients with an early onset of disease also have expression of B cell- and immunoglobulin-related genes in peripheral blood.⁶⁴ The B cell signature, as well as frequent ANA positivity in oligoarthritis patients, has led some authors to suggest a major role for B cells in the pathogenesis of this subtype.⁶⁴

INNATE IMMUNE SYSTEM

KEY POINTS

Defects in the innate immune system have been most closely associated with systemic JIA.

Neutrophils and monocytes secrete myeloid-related protein 8/14, IL-6, IL-1 β , and TNF, which drive systemic inflammation.

Many cytokines detectable in the inflamed joint are the products of the innate immune system. The successful targeting of these cytokines with biologic agents (e.g., IL-1 β and IL-6) heavily implicates the innate immune system in the pathology of JIA, particularly the sJIA subtype.

Macrophages/Monocytes

Monocytes and their tissue counterparts, macrophages, are key effector cells of the innate immune system and have

been linked to the pathogenesis of autoimmune arthritis for several decades.⁶⁵ In JIA, analysis of gene expression has detected an activated macrophage gene expression signature in the cells within synovial fluid of early oligoarthritis patients at risk of extension⁶⁶ and a monocyte signature in the peripheral blood of patients with an older-onset oligoarthritis,⁶⁴ as well as RF-positive polyarthritis patients.⁶⁷ Monocytes typically make up equivalent proportions of synovial fluid and peripheral blood mononuclear cells ($\approx 10\%$), but they have a highly activated phenotype, secreting high levels of IL-6, IL-1 β , and TNF within the joint.^{66,68} Synovial monocytes also secrete vascular endothelial growth factor (VEGF) and osteopontin (OPN), which contribute to the vascularity of inflamed pannus,⁶⁹ and the chemokine CCL20, which drives Th17 cell recruitment to the joint.^{11,70}

Neutrophils

Neutrophils may make up the major fraction of the synovial infiltrate but have remained an infrequent research interest in JIA. sJIA patients have high levels of the heterodimeric myeloid related protein (MRP) 8/14 secreted by activated monocytes and neutrophils.⁷¹ Roth and colleagues⁷² have shown that MRP 8/14, although secreted by cells of the innate immune system, induces autoreactive CD8⁺ T cells, illustrating how cross-talk between the innate and adaptive immune system can lead to chronic inflammation.

Examination of neutrophils from JIA has found more than 700 genes that are differentially expressed in patients' blood compared to controls.⁷³ Genes linked to IL-8 and IFN- γ were prominent among these differences but failed to return to baseline levels after clinical remission. Rather, disease quiescence was associated with an increase in regulatory genes, such as transforming growth factor- β (TGF- β) and retinoic acid, suggesting that remission reflects a balanced state of inflammation and regulation rather than true immunologic resetting.

Stromal Cells

Resident tissue stromal cells are important targets of both the innate and adaptive immune system and may play an important role in defining the anatomic location of inflammation after systemic immune dysregulation. Synovial fibroblasts from JIA patients secrete metalloproteinases and chemokines in response to locally secreted proinflammatory cytokines⁷⁴ and may be an important therapeutic target of the future.⁷⁵

DISEASE SUBTYPE-SPECIFIC PATHOGENESIS

KEY POINTS

Excessive secretion of IL-1 β and IL-6 contributes to many of the clinical features seen in patients with sJIA.

The balance between inflammatory and regulatory T cell populations may determine the severity of clinical course in oligoarticular forms of JIA.

RF-negative polyarthritis shares immunopathologic features with oligoarthritis subtype, whereas RF-positive polyarthritis patients are more closely aligned with RA.

In ERA, HLA-B27 protein is prone to misfolding generating an unfolded protein response within cells, which leads to inflammation and arthritis.

Psoriasis and psoriatic arthritis have been strongly linked to pathogenic T cells secreting IL-22 and IL-17.

Systemic Juvenile Idiopathic Arthritis

A key role for IL-1 β , IL-6, and IL-18, cytokines of the innate immune system, as well as the absence of auto-antibodies or a strong association with MHC, have led many to propose sJIA as an autoinflammatory disease. This hypothesis is supported by the close mirroring of these cytokines with the characteristic fever of sJIA,⁷⁶ the high levels of IL-6 and IL-18 in serum from active sJIA patients,^{43,77} and enrichment of monocytes in sJIA blood,⁷⁸ secreting high levels of IL-1 β after activation. Early studies reported a significantly higher ratio of IL-1 receptor antagonist (IL-1ra) to IL-1 in these sJIA patients,^{76,79} although this may be difficult to interpret because IL-1 α and IL-1 β are highly labile in serum. Early evidence of successful treatment with a soluble IL-1, anakinra, at least for some patients with sJIA supports a role for IL-1.^{80,81} Interestingly, IL-1 β secretion in sJIA may be mediated by MRP 8/14 because once this protein is removed from JIA serum, the potential to induce IL-1 β is almost completely attenuated.⁸² This study confirmed that levels of serum MRP 8/14 are high in active sJIA and that this measure is both sensitive and specific in distinguishing sJIA from other important diagnoses such as infection or hematopoietic malignancy.

IL-18, a macrophage-derived proinflammatory cytokine with a similar signal transduction pathway to IL-1 β , is also grossly elevated in JIA with serum levels correlating with disease activity.⁸³ High IL-18 levels may account for the defective NK cytotoxic function found in sJIA. Follow-up studies of anakinra have cast doubt on the primacy of IL-1 β in sJIA because more than 50% of patients are either non-responders or relapse on treatment. Even in responders, it is likely that other inflammatory mediators are involved because treatment response to anakinra fails to correlate with either pretreatment IL-1 β or IL-18 secretion⁸⁴ or changes in gene expression of the IL-1 β pathway.⁸⁵

IL-6 is another key player in the pathogenesis of sJIA, secreted by a range of cells including monocytes. IL-6 levels are elevated in the serum and synovial fluid of sJIA patients, and levels correlate with disease activity.³³ Spikes and falls in fever are secondary to the circadian rhythm of IL-6,⁷⁶ and many clinical features including growth failure and osteoporosis can be explained by high levels of IL-6.⁸⁶ Trial data show efficacy of IL-6 blockade with the monoclonal antibody to soluble IL-6 receptor, tocilizumab. A trial of tocilizumab demonstrated impressive results with 86% of patients achieving an ACR50 response⁸⁷ (see Chapter 107). IL-6 expression is upregulated by IL-1 β , so the success of IL-6 blockade may represent its role as the final common pathway for inflammation, both IL-1 dependent and independent.

Gene expression profiling from sJIA patients has confirmed pathways that involve IL-6 and IL-1 and that can distinguish active from inactive patients.⁸⁸ In addition to these roles for monocytes in sJIA, defects of NK cell function, in particular perforin function, are well recognized.⁸⁹ The defect in perforin function in active sJIA has been seen to reverse on successful treatment with autologous stem cell transplantation.⁹⁰

Macrophage Activation Syndrome

MAS is a potentially life-threatening complication of sJIA (as well as sometimes complicating other rheumatologic conditions such as JSLE) that results from immune activation of pathogenic T cells and hemophagocytotic macrophages.⁹¹ These macrophages express CD163, a scavenger receptor that recognizes haptoglobin-hemoglobin (HP-Hb) complexes. Increased uptake of these complexes within the macrophage leads to production of ferritin, explaining the hyperferritinemia associated with MAS. Soluble forms of CD25, the α chain of the IL-2 receptor expressed on T cells, and CD163 are useful biomarkers for MAS in JIA.⁹²

MAS shares many similarities with a group of inherited disorders called hemophagocytic lymphocytic histiocytosis (HLH). Defects in the perforin gene and related genes involved in its cytosolic secretory pathway (MUNC13-4, Rab27a, and SH2D1A) have been identified as causes of HLH. When examined in JIA, polymorphisms in MUNC13-4 and perforin have been associated with MAS in some studies^{93,94} but not others.⁹⁵ How defects in cytotoxic function lead to MAS is still unclear, but it has been proposed that appropriate clearance of microbial antigens or activated macrophages is prevented, leading to chronic immune stimulation.

A recent gene expression profiling study of active sJIA showed that patients with active sJIA, and in particular those with MAS, have a signature in PBMC that is similar to patients with familial HLH and characteristic of immature erythropoiesis.⁹⁶

Oligoarthritis

There is increasing evidence that the balance between inflammation and regulation plays a role in driving the clinical phenotype of oligoarthritis patients.⁹⁷ The dominance of Treg within the joints of patients with persistent oligoarthritis may explain the relatively benign prognosis of this subgroup, in contrast to the extended subgroup that has a low ratio of Treg to Th17 cells. Those who remain in the mild prognosis group have higher numbers of regulatory T cells in the joint, both as defined by CD25 or Foxp3 expression,^{11,50} as well as of CD30⁺ Treg cells, which are specific to the human self-antigen hsp60,⁹⁸ and these CD30⁺ regulatory cells have recently been shown to reside within the Foxp3⁺ population.⁵²

Although oligoarthritis JIA patients all present with few joints involved and apparently mild disease, evidence suggests that underlying differences between the groups that remain mild and those that go on to extend are present even early in disease. Thus genetic differences between persistent and extended oligoarticular phenotypes include

variation in the MHC class I allele associations²⁶ and IL-10.⁹⁹ A recent study using gene expression, cellular and cytokine profiling showed that those children destined to go on to extend had a more heavily IFN- γ -driven and activated macrophage signature in synovial cells, as well as differences in levels of the chemokine RANTES (CCL5), from the start of disease even before extension occurs.⁶⁶ Similarly, proteomic profiles have been shown to be distinct, early in disease, in those who go on to extended disease.¹⁰⁰ These data have led to the concept of a separate group of patients with oligoarthritis who are destined to progress to more severe disease, the so-called extended-to-be group.⁶⁶ There is strong evidence to link Th17 cells with autoimmune uveitis, and so agents targeting IL-17, currently under trial in RA, may ameliorate both joint and eye disease in extended oligoarticular JIA.

Rheumatoid Factor–Positive Polyarthritis

The presence of RF and a severe erosive disease course suggests that children in this subgroup represent an early presentation of adult-onset RA. Indeed, this subtype of JIA shares genetic associations with adult rheumatoid arthritis, including the HLA DRB1 locus, in particular the association with the DRB1*0401 allele at this locus.¹⁰¹ However, few studies have directly compared immunology between adult and childhood onset of disease. Studies of ACPA positivity in children with JIA have shown association with RF-positive polyarticular disease,¹⁰² and there is evidence to support a pathogenic role for RF and associated autoantibodies against citrullinated peptides by fixation of complement on synovial endothelium.¹⁰³ In animals, transfer of ACPAs does not lead to arthritis but enhances tissue injury when there is a background of low-grade joint inflammation.⁷² Children with RF-positive polyarthritis may share histologic features with adult RA patients, with lymphoid follicles and germinal centers that may be more abundant than in RF-negative patients.^{62,104}

Rheumatoid Factor–Negative Polyarthritis

RF-negative polyarthritis represents a more heterogeneous group than RF-positive polyarthritis, with several studies suggesting clinically distinct subgroups (see Chapter 107). Analysis of gene expression data from polyarthritis patients showed three separate signatures.⁶⁷ The first was associated with monocyte-related genes and had the highest proportion of RF-positive patients. The third signature found in RF-negative patients was associated with reduced CD8⁺ T cells and increased plasmacytoid DC. Interestingly, patients did not have overlap between signatures 1 and 3, suggesting distinct immunopathology. It is noteworthy that a significant proportion of patients (24 out of a total of 61) who were younger and had a higher rate of ANA positivity did not fall in a clearly distinct category. A further gene expression study suggested these patients may overlap with ANA-positive oligoarthritis patients and that age of onset of disease is a more important distinguishing factor than the number of involved joints.⁶⁴ These data are consistent with results of cytokine levels in plasma and synovial fluid from oligoarthritis and polyarthritis.¹⁰⁵ Both subtypes clustered together and were distinct from sJIA and RA patients. As

discussed, there are similar immune pathways in RF-negative polyarthritis and oligoarthritis patients, and overall disease expression may depend on the balance between immune regulation and inflammation.

Enthesitis-Related Arthritis

The HLA-B27 allele, recognized many years ago for its association with autoimmune arthritis, appears to play a particular role in pathogenesis through its molecular properties. The presence of a cysteine residue at position 67 of the HLA-B27 $\alpha 1$ helix heavy chain makes possible a disulfide bond that promotes the formation of homodimers of the B27 chain.¹⁰⁶ These homodimers, which can form in the absence of antigenic peptide and can induce ER stress,¹⁰⁷ have been shown to be proinflammatory and to be ligands for NK cell receptors such as KIR3DL1 and KIR3DL2¹⁰⁸ (see also Chapter 74).

Cells expressing HLA-B27, which is prone to this abnormal folding of the HLA molecule, and which in the context of microbial antigens drives high expression of IL-23, may contribute to factors promoting Th17 cells.¹⁰⁹ This hypothesis may also explain the association between ERA and inflammatory bowel disease because Th17 cells also drive pathology in the latter condition and pathogenic cells readily recirculate from gut to joint. Patients with ERA may be particularly prone to disease induction by bacterial pathogens because cells from patients have high expression of pathogen recognition molecules TLR2 and TLR4 when compared with healthy controls.¹¹⁰ Along with putative misfolding in the ER by HLA-B27, this allele may alter the antigenic peptides available for T cell recognition.¹¹¹ It is interesting that ERAP1, which is strongly associated with adult ankylosing spondylitis (AS), is also associated with pediatric-onset ERA.⁴² This protein is thought to affect the repertoire of peptides available to bind class I MHC, by cleavage of N-terminal amino acids from peptide precursors in the ER.¹¹²

Psoriatic Arthritis

The etiology of psoriatic arthritis shares features with enthesitis-related arthritis, having a genetic association with MHC class I loci, a clonal expansion of CD8 T cells in inflamed joints,¹¹³ and a putative role for Th17 cells. Certainly in adult psoriasis and psoriatic arthritis there is strong evidence that Th17 cytokines IL-22 and IL-17 contribute to the disease process.^{114,115} The receptor for IL-23, a key cytokine that induces Th17 cells, is linked to the juvenile form of the disease and IL-23 blockade appears promising in trials of skin and joint disease in adult patients.¹¹⁶ The innate immune system may also play a role because a recent study found genetic associations with autoinflammatory genes in juvenile psoriatic arthritis patients.¹¹⁷

TRANSLATION FROM UNDERSTANDING PATHOGENESIS TO CLINICAL PRACTICE

The heterogeneity of childhood arthritis is complex but is gradually being characterized and harnessed, through the

application of novel methods including gene expression profiling, proteomics, and high-throughput genetics. Major progress in the understanding of immunologic processes involved has occurred. In this chapter, cellular processes at play in JIA have been considered. The immune system acts in concert to create vastly complex networks. The challenge is to understand the functional hierarchy of these networks and discover checkpoints that will be amenable to therapeutic targeting in the future.

In addition to new treatments, better biomarkers are required for use in the clinic. For example, in the case of MAS, as knowledge of pathogenesis improves, more biomarkers will become available to predict adverse outcomes.¹¹⁸ The task in coming years will be to integrate the vast body of data that will be generated through these novel approaches in order to allow the development of more precise classification definitions and, perhaps more importantly, predictive tools and algorithms with which to drive treatment choices for patients and so allow accurate stratification for those who should receive novel biologic agents (e.g., TNF or IL-6 blockade) early in their disease, to achieve early remission.

Treatment of Juvenile Idiopathic Arthritis

JOYCE J. HSU • TZIELAN CHANG LEE •
CHRISTY I. SANDBORG

KEY POINTS

Juvenile idiopathic arthritis (JIA) is the umbrella term for the family of childhood arthritides of unknown cause.

JIA affects at least 1 in 1000 children.

Before wide use of methotrexate and biologic therapies, 50% of children with JIA would reach adulthood with significant disabilities.

The goals of treatment in JIA are complete suppression of inflammation on medications and remission when possible.

Oligoarticular JIA, characterized by early age of onset, female predominance, antinuclear antibody positivity, and frequent subacute anterior uveitis, occurs only in childhood.

Systemic JIA is distinct from other subgroups of JIA in its equal sex distribution, lack of autoantibodies and human leukocyte antigen associations, and increased responsiveness to interleukin (IL)-1 and IL-6 inhibition compared with tumor necrosis factor inhibition.

Enthesitis-related arthritis typically occurs in children greater than 6 years of age, but sacroiliitis may not develop until adolescence.

Arthritis in a child can result in overgrowth (in the knee causing length discrepancy) and undergrowth (in the temporomandibular joint causing micrognathia) of joints.

Because bone erosions on conventional radiographs are late radiographic findings in growing children, early joint damage may require different imaging modalities.

Considerable progress in understanding the genetics and pathogenesis of JIA has revealed subtype-specific associations, as well as some common mechanisms of disease that will translate to more effective and targeted therapies.

Juvenile idiopathic arthritis (JIA) is the most common rheumatic disease in childhood, but actual estimates of prevalence and incidence vary remarkably in different geographic regions, ranging from 7 to 400 per 100,000 children, reflecting variations in disease reporting, classification, and ethnic and environmental differences in disease expression.¹ Reasonable working estimates are 150 per 100,000 children, which makes JIA one of the most common chronic diseases of childhood. There are significant differences in the disease manifestations in children compared with adults, with some types occurring exclusively in children. This chapter discusses the current understanding of the key clinical features of the various forms of JIA, differential diagnoses, treatment approaches, prognosis, and outcomes. The rapid growth in understanding the biologic basis for JIA and

the ongoing development of targeted therapies for rheumatic diseases are likely to lead to enhancements in these recommendations. Data concerning long-term disease course and outcome in children with JIA in this modern treatment era remain limited, and there are international prospective inception cohorts of children with arthritis designed to address these gaps in knowledge.^{2,3}

CLASSIFICATION CRITERIA FOR JUVENILE IDIOPATHIC ARTHRITIS

Differential Diagnosis

In the past, different groups had used various types of nomenclature to classify children with persistent arthritis including “juvenile rheumatoid arthritis” (American College of Rheumatology [ACR]) and “juvenile chronic arthritis” (European League Against Rheumatism), which created problems in comparing research studies and outcomes. The goal of the International League of Associations for Rheumatology (ILAR) is to identify subtypes of JIA for research purposes that are homogeneous and mutually exclusive. JIA classification is currently based on predominant clinical and laboratory features and the number of involved joints at disease onset.⁴ There is a continual renewal process, with the second revision occurring in Edmonton in 2001, which is presented in [Table 107-1](#). However, classification systems are ever evolving, and categorization may evolve to more biologically and genetically similar subgrouping, especially with recent advances in etiology and pathogenesis. For example, age of onset may be a more biologically relevant parameter to distinguish between subtypes of JIA than classification based on number of involved joints. PBMC gene expression analysis reveals biologic differences between patients with early-onset (<6 years) and late-onset (>6 years) JIA, which was independent of oligoarthritis or polyarthritis subtype.⁵ Ravelli and colleagues⁶ provided clinical support for this approach, showing that antinuclear antibody (ANA)-positive patients with oligoarthritis and rheumatoid factor (RF)-negative polyarthritis were similar in terms of early age at onset, female predilection, increased frequency of asymmetric arthritis, and increased frequency of uveitis.

Pattern recognition is perhaps the most significant skill needed by clinicians in the diagnostic evaluation of patients. The usual patterns in children with rheumatic diseases often overlap with malignancies, infection, and trauma (especially nonaccidental). Therefore it is crucial to evaluate these diagnostic possibilities first before accepting the diagnosis of JIA. The ILAR categories are meant to simplify classification and are useful for typical presentations of

Table 107-1 International League of Associations for Rheumatology Classification Criteria for Juvenile Idiopathic Arthritis (JIA)⁴

General definition of JIA: arthritis of unknown etiology that begins before the sixteenth birthday and persists for at least 6 wk; other known conditions are excluded		
Subcategory	Definition	Exclusions
Oligoarthritis 1. Persistent oligoarthritis: Affecting ≤4 joints throughout the disease course 2. Extended oligoarthritis: affecting a total of >4 joints after the first 6 mo of disease	Arthritis affecting 1-4 joints during the first 6 mo of disease	a. Psoriasis or a history of psoriasis in the patient or first-degree relative b. Arthritis in an HLA-B27–positive male beginning after the sixth birthday c. Ankylosing spondylitis, ERA, sacroiliitis with inflammatory bowel disease, reactive arthritis, acute anterior uveitis, or a history of one of these disorders in a first-degree relative d. The presence of IgM RF on at least 2 occasions at least 3 mo apart e. The presence of systemic JIA in the patient
RF-Negative Polyarthritis	1. Arthritis affecting ≥5 joints during the first 6 mo of disease and 2. Test for RF is negative	a, b, c, d, e
RF-Positive Polyarthritis	1. Arthritis affecting ≥5 joints during the first 6 mo of disease, and 2. ≥2 positive RF tests (as routinely defined in an accredited laboratory), at least 3 mo apart during the first 6 mo of disease	a, b, c, e
Psoriatic Arthritis	1. Arthritis and psoriasis, or 2. Arthritis and at least 2 of the following: 1. Dactylitis 2. Nail pitting (minimum of 2 pits on 1 or more nails at any time) or onycholysis 3. Psoriasis in a first-degree relative	b, c, d, e
Enthesitis-Related Arthritis	1. Arthritis and enthesitis, or 2. Arthritis or enthesitis, with at least 2 of the following: a. The presence of or a history of sacroiliac joint tenderness and/or inflammatory lumbosacral pain b. The presence of HLA-B27 c. Onset of arthritis in a male >6 yr of age d. Acute (symptomatic) anterior uveitis e. History of ankylosing spondylitis, ERA, sacroiliitis with inflammatory bowel disease, reactive arthritis, or acute anterior uveitis in a first-degree relative	a, d, e
Systemic JIA	Arthritis in 1 or more joints with, or preceded by, fever of at least 2 weeks' duration that is documented to be daily and quotidian (fever that rises to ≥39° C once a day and returns to ≤37° C between fever peaks) for at least 3 days, and accompanied by 1 or more of the following: 1. Evanescent (nonfixed) erythematous rash 2. Generalized lymph node enlargement 3. Hepatomegaly and/or splenomegaly 4. Serositis	a, b, c, d
Undifferentiated Arthritis	Arthritis that fulfills criteria in no category or in ≥2 of the above categories	

ERA, enthesitis-related arthritis; RF, rheumatoid factor.

disease. However, if a patient does not easily fit into the ILAR classification system, clinicians must carefully consider all other possibilities, rheumatologic and nonrheumatologic. To this end, ILAR recommends the following descriptors in order to obtain more clinical information: age at onset; characteristics of articular involvement; serologies (ANA, RF, anticitrullinated protein antibody [ACPA]); uveitis; and the human leukocyte antigen (HLA) allelic associations. For example, a 2-year-old girl who wakes up crying at night from back or hip pain should immediately trigger alarms of infection or malignancy rather

than a rheumatic condition. This case is different from a 12-year-old boy with back stiffness and hip and enthesal pain, which would be a classic presentation of enthesitis-related arthritis (ERA) in this age group.

Among patients with acute lymphocytic leukemia (ALL), 15% to 30% present with musculoskeletal symptoms and may be misdiagnosed as JIA.⁷ Up to 75% of children ultimately diagnosed with ALL presenting with musculoskeletal complaints did not have blasts in the peripheral blood at the time of evaluation by pediatric rheumatologists, although low white blood cell count, mild

thrombocytopenia, and nighttime pain were early indicators of ALL. ANA status, rash, radiographic abnormalities, and objective signs of arthritis were not helpful in distinguishing between ALL and JIA because they occurred at similar rates in both groups.⁸

Each subcategory is discussed later, focusing on clinical manifestations, diagnostic features, treatment, outcome, and prognosis. Treatment recommendations are discussed later for each of the subtypes of JIA on the basis of current available evidence including the recently developed ACR recommendations for the treatment of JIA.⁹

RHEUMATOID FACTOR–NEGATIVE POLYARTHRITIS

Clinical Manifestations and Diagnostic Features

RF-negative polyarthritis makes up 10% to 30% of all JIA cases, with a bimodal distribution of age of onset with the first peak at 1 to 4 years of age and the second peak at 10 to 12 years. Girls are more commonly affected than boys with a ratio of 3.2:1, and subacute anterior uveitis occurs in 4% to 25%.¹⁰ Any joint may be affected in RF-negative polyarthritis JIA, with more involvement of hip, shoulder, cervical spine, and distal interphalangeal joints than in adults. The arthritis is often usually insidious and can be symmetric or asymmetric, affecting both large and small joints. Some authors distinguish between two clinical subgroups on the basis of ANA status: (1) an ANA-positive form that resembles oligoarthritis, except for the number of joints affected in the first 6 months of disease, consisting of young girls (younger than age 6) with an asymmetric-onset arthritis and at a high risk of uveitis, and (2) an ANA-negative form that is similar to adult-onset RF-negative rheumatoid arthritis (RA), characterized by symmetric synovitis of large and small joints, with onset in a slightly older age group (ages 7 to 9). The similarities between ANA-positive, RF-negative polyarthritis and oligoarthritis have led to the hypothesis that these two entities are actually in the same disease spectrum.⁶

RF-negative polyarthritis may be associated with elevated acute phase reactants, mild anemia, and ANA positivity in up to 40%. Even though RF is negative, 50% to 80% of patients are ACPA positive,¹⁰ using high-sensitivity (but low-specificity) testing methods.¹¹

Differential Diagnosis

The differential diagnosis of RF-negative polyarthritis includes the other JIA subtypes including ERA, which should be considered particularly in boys older than 6 years of age because sacroiliac involvement may not occur until adolescence. Other major diagnostic considerations include other rheumatic conditions such as lupus, especially in an older girl who is ANA positive; lymphoma; and leukemia. *Neisseria gonorrhoeae* and Lyme disease can present as an acute polyarthritis.

Treatment

With the current development of increasingly more effective biologic treatment for arthritis, pediatric

rheumatologists now aim to achieve complete disease remission as early as possible in the disease course. Several studies support the paradigm of treating aggressively to reach inactive disease as early as possible, which may ultimately lead to better outcome such as improved quality of life, shorter periods of time spent in active disease, and less long-term joint damage. Active disease in the first 2 years was significantly associated with the duration of active disease in the following 3 years,¹² and conversely, improved disease control with disease-modifying antirheumatic drugs (DMARDs) and/or biologics was associated with improved outcomes.¹³ To this end, children with polyarthritis require a disease-modifying agent as soon as practically possible after the diagnosis has been confirmed. If nonsteroidal anti-inflammatory drugs (NSAIDs) are initially used as monotherapy, with or without intra-articular steroids (IASs), continued disease activity at no more than 2 months should prompt escalation of therapy.⁹ As shown in Figure 107-1, methotrexate (MTX) is the first DMARD of choice, but if there is an inadequate response to MTX by 2 months, anti-tumor necrosis factor (TNF) agents should be initiated.^{14,15} The different TNF inhibitors have not been directly compared against each other, so it is not possible to determine which might be most effective and safe in a given patient. Switching between TNF inhibitors in children has not been well studied. Sulfasalazine and leflunomide can still be used before an anti-TNF agent in mild disease, although evidence suggests that leflunomide may be slightly less effective than MTX.¹⁶ Polyarticular disease course of any type, which does not respond well to MTX or anti-TNF agents, is now increasingly being treated with a range of newer biologics. Physiotherapy (PT) is important for all children with JIA, for stretching, muscle building, and consequent joint protection. Children with hand involvement need occupational therapy (OT) assessment and input regarding writing and school accommodations. The following paragraphs summarize specific information about different therapies used in children and may be applied to all types of JIA as appropriate. (See Table 107-2 for medications, dosing, route, and safety monitoring recommendations.)

Nonsteroidal Anti-inflammatory Drug Use in Children

NSAIDs may help control symptoms but do not alter the natural history of JIA. In general, NSAIDs should only be considered as monotherapy in initial therapy in low disease activity. If control is not achieved in 1 to 2 months, additional therapy should be considered.⁹ NSAIDs are frequently used for symptom control as an adjunctive therapy to more definitive therapies. Gastric protection with H₂ blockers or proton pump inhibitors may be required.

Intra-articular Steroid Injections

The use of intra-articular triamcinolone hexacetonide (THA), 1 mg/kg in large joints such as the knee and 0.5 mg/kg in smaller joints such as the ankle, has been found to be superior to triamcinolone acetate, betamethasone, and methylprednisolone acetate in randomized controlled trials.¹⁷⁻²² Early treatment is associated with better outcome,²³ and IASs are expected to result in clinical improvement of

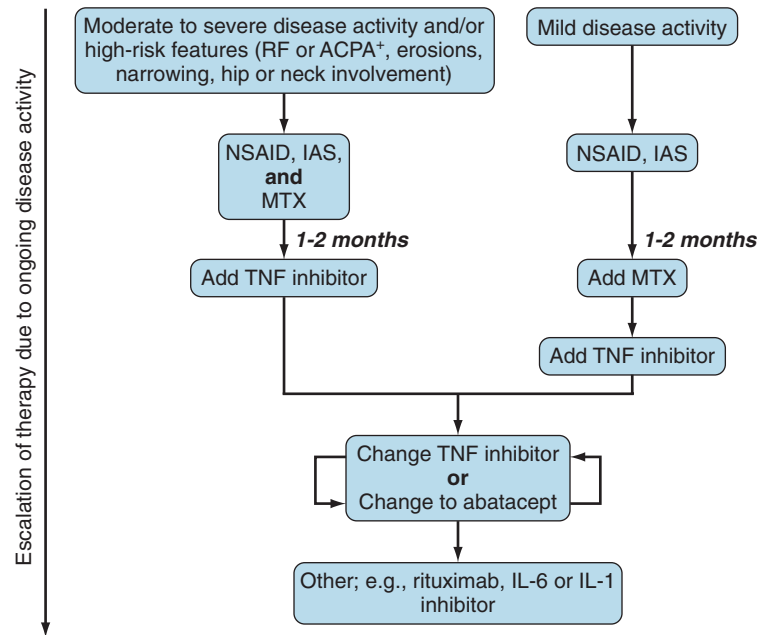

Figure 107-1 Polyarticular-course juvenile idiopathic arthritis treatment algorithm including rheumatoid factor (RF)-negative, RF-positive, extended oligoarticular, and psoriatic arthritis treatment. The treatment goal is remission of disease activity and is stratified by severity of disease. More disease activity or high-risk features should prompt disease-modifying antirheumatic drug use as initial therapy, whereas nonsteroidal anti-inflammatory drug (NSAID) monotherapy could be used initially for 1 to 2 months. If NSAID monotherapy is ineffective, treatment should be escalated. ACPA, anticitrullinated protein antibody; IAS, intra-articular steroid; IL, interleukin; MTX, methotrexate; TNF, tumor necrosis factor.

arthritis for at least 4 months. Therefore if arthritis recurs, joint injections can be repeated up to three times in a 12-month period. Difficult-to-reach joints such as the hip, sacroiliac (SI) joint, temporomandibular joint (TMJ), and subtalar joint may be injected using ultrasound or fluoroscopy. IASs should be administered under sedation or general anesthesia for the young. The use of IASs for active arthritis has been recommended by the ACR guidelines regardless of concurrent therapy, JIA subtype, disease activity, prognostic features, or joint contracture. If the duration of clinical improvement is shorter than 4 months, systemic treatment (e.g., MTX) may be indicated.⁹

Corticosteroid Use in Children with Juvenile Idiopathic Arthritis

In general, systemic corticosteroids should be used sparingly in the treatment of any subgroup of JIA because of the severe morbidity associated with chronic use, even at low doses. Newer therapeutic modalities such as biologics reduce the dependence for any corticosteroids and/or limit the doses needed. The evidence for use of corticosteroids for the synovitis of JIA is controversial and conflicting, and the ACR recommendations for JIA treatment were unable to make any recommendations for corticosteroid use, except in systemic juvenile idiopathic arthritis (sJIA) for severe systemic features.⁹ However, in some cases, low doses of corticosteroids (<0.1 mg prednisone equivalent/kg/day) or brief high-dose regimens (intravenous methylprednisolone 30 mg/kg/day for 1 to 3 days) may be used in polyarticular JIA, in order to bridge constitutional features of pain and fatigue while waiting for DMARDs or biologic therapies to reach their therapeutic effect. Local use of corticosteroids for uveitis is discussed later in “Uveitis.”

Methotrexate

MTX is the most commonly used DMARD in JIA.²⁴ In a retrospective cohort study involving all JIA subtypes, the strongest predictor of response to MTX at 6 months of treatment was the time from diagnosis to start of MTX, suggesting that starting MTX early will lead to a better response.²⁵ The ACR guidelines support a maximum dose of 0.6 mg/kg once weekly (equivalent to 15 mg/m²/week, maximal 25 mg/week) of parenteral MTX.⁹ In patients with lower disease severity, lower doses (8 to 12.5 mg/m²/week oral or parenteral) may be effective, and these doses are similar in safety.¹⁵ Most pediatric rheumatologists start folic acid at 1 mg/day, but daily folate supplementation remains controversial. Routine monitoring of liver enzyme tests should be done as noted in Table 107-2, but liver biopsies are not indicated except in unusual circumstances. Some children develop an intolerance to MTX, and leflunomide may be used as an alternative.^{16,26} Both MTX and leflunomide are associated with teratogenic effects.

Tumor Necrosis Factor Inhibitors

Anti-TNF agents are effective in many children with polyarticular-course JIA of any onset type who fail to respond fully to MTX. The first TNF inhibitor to be studied in JIA, etanercept, demonstrated efficacy and safety in a novel randomized withdrawal trial design in patients with polyarticular JIA, in which the study design was based on an open-label period, followed by randomization of responders to placebo or study drug with the primary endpoint being time to flare.¹⁴ Since that initial randomized control study in 2000, long-term studies and registries have continued to demonstrate the safety and efficacy of etanercept in children

Table 107-2 Commonly Used Medications in Juvenile Idiopathic Arthritis^{9,176}

Medication	Typical Maximum Dose	Typical Frequency
Abatacept	10 mg/kg (max 1000 mg) IV	Load at 0, 2, 4 wk, then every 4 wk
Adalimumab	24 mg/m ² <30 kg: 20 mg SQ >30 kg: 40 mg SQ	Every 2 wk
Anakinra	2 mg/kg (max 100 mg) SQ	Daily
Cyclosporine	6 mg/kg/day orally	Divided twice a day
Diclofenac (SR preparation available)	1-3 mg/kg/day (max 150 mg/day)	Divided 1-3 times a day
Etanercept	0.8 mg/kg/wk (max 50 mg)* SQ 0.4 mg/kg/dose (max 25 mg) SQ	Once weekly 2×/wk
Ibuprofen	≥6 mo of age: 30-40 mg/kg/day	Divided 3-4 times a day
Indomethacin (SR preparation available)	>1 mo of age: 1-2 mg/kg/day (max 50 mg/day)	Divided 1-2 times a day
Infliximab	10 mg/kg/dose IV	Load at 0, 2, 6 wk, then every 4 wk
Intravenous immunoglobulin	2 g/kg/dose IV	Every 2 wk
Leflunomide	<40 kg: 10 mg orally >40 kg: 20 mg orally	Daily
Methotrexate	15 mg/m ² /dose SQ (0.6 mg/kg; max 25 mg)	Weekly
Naproxen	>2 yr of age: 20-30 mg/kg/day (max 1 g/day)	Divided twice a day
Piroxicam	<15 kg: 5 mg orally 16-25 kg: 10 mg orally 26-45 kg: 15 mg orally >46 kg: 20 mg orally	Daily
Rilonacept	2.2-4.4 mg/kg SQ	Once weekly
Rituximab	750 mg/m ² (max 1000 mg) IV	Twice 2 wk apart
Sulfasalazine	50 mg/kg/day (max 2 g) orally	Divided twice a day
Tacrolimus	0.2 mg/kg/day orally	Divided twice a day
Thalidomide	5 mg/kg/dose orally	Daily
Tocilizumab	<30 kg: 12 mg/kg IV >30 kg: 8 mg/kg IV	Every 2 wk

*The effectiveness of the 0.8 mg/kg/wk dose has been evaluated in JIA patients.^{177,178}
IV, intravenous; SQ, subcutaneous; SR, sustained release.

Summary of Recommendations for Medication Safety Monitoring

Nonsteroidal Anti-inflammatory Drugs

Complete blood count, liver enzymes, serum creatinine
Before or soon after initiation of routine use
Repeat approximately twice yearly for chronic daily use
Repeat approximately once yearly for routine use (3-4 days/wk)

Methotrexate

Complete blood count, liver enzymes, serum creatinine
Before initiation
Approximately 1 mo after initiation
Approximately 1-2 mo after increase in dose
Repeat approximately every 3-4 mo if prior results normal and dose stable

Tumor Necrosis Factor Inhibitors

Complete blood count, liver enzymes, serum creatinine
Before initiation
Repeat approximately every 3-6 mo
Tuberculosis screening
Before initiation
Repeat approximately once yearly

with polyarthritis, with and without MTX.²⁷⁻³² The frequency of major serious adverse events (SAEs) have been low, with adjusted rates of 0.12 events per patient year and 0.03 medically important infections per patient year in open-label extensions.³⁰ Importantly, no cases of lupus, demyelinating disorders, malignancies, opportunistic infections, or tuberculosis were seen. Although there have been several long-term studies of etanercept with international registries, the total number of patient-years available for evaluation is still too small to be able to detect rare long-term SAEs such as malignancy or demyelinating diseases.

A 1-year prospective, observational study to compare combination etanercept and MTX with etanercept monotherapy demonstrated that the likelihood of achieving 70% disease control (ACR Pedi 70) was increased with combination therapy (odds ratio of 2.1, 95% CI 1.2 to 3.5) as compared with etanercept monotherapy.²⁷ In this cohort, there were 24 infectious SAEs and 23 noninfectious SAEs including three malignancies in 496 patients over 12 months. Growth delay in JIA was improved and reversed with the use of etanercept.³³

An international, multicenter, randomized, double-blind, placebo-controlled trial of infliximab provided

important lessons regarding dosing in children.³⁴ The initial dose of 3 mg/kg/infusion based on adult studies did not demonstrate efficacy at 3 months compared with placebo; however, a separate arm suggested that 6 mg/kg/infusion had better pharmacokinetics leading to better effectiveness. In a 4-year, long-term, open-label extension, 14% of patients discontinued infliximab due to SAEs including six infectious SAEs in 120 patients over 52 weeks.³⁵ Significant infusion reactions associated with infliximab antibodies and asymptomatic development of antinuclear antibodies were observed.

Adalimumab was shown to be efficacious and safe in a randomized placebo-controlled withdrawal trial in patients with moderately to severely active polyarticular JIA with or without MTX, and there was a trend toward more improvement with combination therapy, although the study was not statistically powered to measure this difference.³⁶ The dose used was adalimumab 24 mg/m² (maximum dose, 40 mg) subcutaneously every other week. SAEs possibly related to adalimumab occurred in 14 patients (total 177), seven of which were serious infections.

In August 2009, the U.S. Food and Drug Administration issued a black box warning on the increased risk of cancer, particularly lymphoma, in children and adolescents receiving TNF inhibitors for arthritis or inflammatory bowel disease (IBD).³⁷ The other adverse events involved with TNF inhibitors are similar to that of adults and have been reported in children as well including serious infections, demyelinating processes, optic neuritis, injection site reactions or infusion reactions, and development of autoimmune conditions. Because of the voluntary nature of reporting rare adverse drug events in the United States, the actual risk of any of these rare events is not known.

Abatacept

The T cell co-stimulatory inhibitor, CTLA4-Ig (abatacept), was studied in an international placebo-controlled randomized withdrawal trial in 190 patients with active polyarthritis regardless of onset type who had inadequate response or intolerance to one DMARD in the past including TNF inhibitors.³⁸ Concurrent MTX was allowed. Thirty-percent improvement (ACR Pedi 30) response rates were 76% in biologic-naïve patients and 39% in patients with prior biologic therapy. Abatacept continued to be clinically significant with durable efficacy in patients with JIA, and some patients require longer periods for optimal response (>3 to 4 months) compared with TNF inhibitors.³⁹ No cases of tuberculosis or malignancy were detected, but patient numbers were small and follow-up time was limited.

Other Biologics

The ACR guidelines recommend consideration of rituximab as a treatment option for patients who have received TNF inhibitor and abatacept sequentially and have high disease activity.⁹ IL-6 and IL-1 inhibition are discussed in more detail later in “Systemic Juvenile Idiopathic Arthritis” but have not been specifically studied in polyarticular disease. The use of nonbiologic DMARD combinations (such as MTX plus sulfasalazine and/or hydroxychloroquine) has not been studied in children.

Outcome

Early response to treatment was an important predictor of long-term outcome.¹³ Symmetric arthritis and early hand involvement predicted future disability and poorer overall well-being.⁴⁰ The ACR guidelines for JIA treatment also consider the following as poor prognostic factors in patients with RF-negative polyarthritis: arthritis of hip or cervical spine; positive ACPAs; and radiographic damage (erosions or joint space narrowing by radiograph).⁹

RF-negative polyarthritis has a variable outcome, which shows the heterogeneity of the subtype,⁴¹ but the overall prognosis appears to be better than RF-positive polyarticular JIA.⁴² Approximately 30% of children will go into long-term remission off medication, with the chance of remission being highest in the first 5 years of disease.^{43,44} However, flare of disease 2 years after reaching clinical remission off medication had occurred in 69% of patients.⁴³

RHEUMATOID FACTOR-POSITIVE POLYARTHRITIS

Clinical Manifestations and Diagnostic Features

RF-positive polyarthritis is a well-characterized JIA subcategory and is part of the same disease spectrum as adult RF-positive RA,⁴⁵ sharing immunogenetic and serologic factors. This subcategory makes up 5% to 10% of cases of JIA¹⁰ and is more common in girls, with reported female-to-male ratios between 5.7 and 12.8:1.0.^{46,47} Age of onset occurs in late childhood or adolescence and typically is an aggressive, symmetric polyarthritis affecting the small joints of the hands, as well as large joint involvement in a pattern that resembles RA. These children frequently have more than 30 joints with arthritis. Hip involvement is common and may be debilitating. The arthritis can be quite severe, often resulting in bony erosions and joint destruction. Radiologic changes tend to take place early,⁴² especially in hands and feet. With active disease, patients may occasionally have mild systemic signs and symptoms such as weight loss, low-grade fever, malaise, mild hepatosplenomegaly, or lymphadenopathy. Rheumatoid nodules occur in up to 10% of cases, most frequently around the elbow. Other extra-articular manifestations are reported less often than in adults. Uveitis is an unusual feature of this subtype, occurring in only about 0% to 2% of patients.¹⁰

Polyarthritis may be associated with mild to moderate inflammation such as elevated acute-phase reactants and a normocytic, normochromic anemia. By definition, all patients have IgM-anti-IgG RF. The ANA test is positive in about 55% of patients,¹⁰ and ACPAs have been reported in 57% to 73%.^{48,49}

Differential Diagnosis

The differential diagnosis of RF-positive polyarthritis includes other JIA subcategories, especially when there is no confirmed RF-positive test on two occasions. Such cases are frequently unclassified in the JIA system; however, management and therapy remain similar.

Treatment

Treatment algorithms and ACR guidelines for patients with all types of polyarthritis are discussed in [Figure 107-1](#). However, because children with RF-positive polyarthritis are at higher risk of prolonged erosive arthritis compared with other types of JIA, these children should be considered to be in the more severe disease category, requiring rapid escalation of treatment if even mild disease activity persists. Rather than an initial period of NSAID monotherapy, RF-positive polyarthritis patients should receive MTX, at the time of diagnosis, with rapid addition of a TNF inhibitor if response is not adequate.⁹ Some children benefit from multiple joint injections to maintain control of the arthritis.

Outcome

Children with RF-positive polyarthritis have a poorer long-term prognosis than the other JIA subcategories.^{42,50} Inactive disease is difficult to achieve with 84% of the disease course consisting of active disease, and only 5% of patients were able to maintain remission after cessation of therapy.⁴³

OLIGOARTICULAR JUVENILE IDIOPATHIC ARTHRITIS

Clinical and Diagnostic Features

Oligoarticular JIA accounts for up to 20% of all new rheumatic diagnoses in the general pediatric rheumatology clinic⁴⁷ and is the most prevalent of all the JIA subcategories, comprising 30% to 60% of all JIA patients in North America and Europe.⁴¹ Oligoarticular JIA has no adult equivalent. The peak age of onset occurs in Caucasian children ages 2 to 4 years from the United States and Europe.¹⁰ Females are affected more commonly than males, 3:1.¹⁰ Two general subgroups are recognized within oligoarticular JIA: extended oligoarticular involvement, in which many additional joints develop arthritis after the initial 6 months, as contrasted to persistent oligoarticular JIA, in which the number of joints affected remains less than 5. Currently,

there is no single reliable predictor of extension, but symmetric disease, ankle and/or wrist involvement, and an elevated erythrocyte sedimentation rate (ESR) in the first 6 months of disease may indicate likelihood of extension.^{51,52} Disease extension to the extended subtype has been reported to be 30% to 50% at 4 to 6 years after disease onset.^{51,53}

Oligoarticular JIA usually presents as an asymmetric arthritis affecting one or two large joints, especially of the lower extremities, with the knee being the most commonly affected, followed by the ankle, wrist, and digits. Hand involvement is the third most commonly affected location, but this pattern may portend the later onset of psoriatic arthritis.⁵⁴ Involvement of the hip and back, especially in young children, is so unusual that extensive evaluation is warranted to rule out other conditions such as infection or tumors.

Significant constitutional and systemic symptoms are unusual in oligoarticular JIA and, if present, should raise concern regarding the accuracy of the initial diagnosis. Pain in an obviously inflamed joint is surprisingly minimal compared with septic arthritis, and in up to 25% of cases the symptoms may be subtle with parents only noticing a limp and joint swelling. In a young child there is reluctance to walk and bear weight with a return to crawling. There is a high risk for developing a relatively asymptomatic chronic uveitis, especially in ANA-positive individuals, requiring regular ophthalmology examinations to detect early changes. (See [Table 107-3](#) for guidelines and “Uveitis” later for treatment.) Other complications that can be prevented in most patients with proper treatment include growth discrepancies in muscle tone and bulk, leg length, and the development of micrognathia and joint contractures.

Among children with oligoarthritis, 75% to 85% have a positive ANA (70% to 80% in persistent oligoarticular JIA and 80% to 95% in extended oligoarticular JIA),¹⁰ with low to moderate titers (1:40 to 1:320). The rate of ANA positivity is even higher in girls with an early onset.⁵⁵ Patients are RF negative, although ACPAs have been detected in some patients with oligoarticular JIA, depending on the enzyme-linked immunoreceptor assay (ELISA) method used for screening.¹¹ Some suggest that ANA serology should delineate a homogeneous group of arthritis patients, independent of the course of arthritis and number of joints involved.⁶

Table 107-3 American Academy of Pediatrics Recommended Ophthalmologic Screening Frequency for Asymptomatic Uveitis in Juvenile Idiopathic Arthritis (JIA) Patients^{*67}

JIA Subtype	Antinuclear Antibody Status	Age of JIA Onset (yr)	Duration of Disease (yr)	Uveitis Risk Category	Eye Examination Frequency (mo)
Oligoarthritis or polyarthritis	+	≤6	≤4	High	3
	+	≤6	>4	Moderate	6
	+	≤6	>7	Low	12
	+	>6	≤4	Moderate	6
	+	>6	>4	Low	12
	–	≤6	≤4	Moderate	6
	–	≤6	>4	Low	12
	–	>6	NA	Low	12
Systemic JIA	NA	NA	NA	Low	12

*Several investigators have recommended the most intensive screening ophthalmologic exams in ANA-positive girls with JIA onset <7 yr of age independent of JIA subtype. Patients with JIA onset <5 yr should have eye exams every 3 mo until 7 yr after JIA diagnosis.⁶⁴ On the other hand, in a large, German, population-based study using the International League of Associations for Rheumatology classification system of JIA, certain modifications were proposed that were less conservative than the American Academy of Pediatrics in terms of frequency of eye exams, so the timing of screening exams remains unclear.⁶⁵

NA, not applicable.

The typical child with oligoarticular JIA will have normal white blood counts, normal or mild to moderately elevated acute-phase reactants, and in some cases, mild anemia. Elevated acute-phase reactants may suggest other conditions with inflammatory features such as IBD or malignancy.

Differential Diagnosis

The differential diagnosis of oligoarticular JIA includes other JIA subtypes, especially ERA and psoriatic JIA; other rheumatic diseases of childhood; and nonrheumatic causes of joint pain and swelling such as septic arthritis, benign or malignant tumors, reactive arthritis, foreign body synovitis, pigmented villonodular synovitis, arterial-venous malformation, bleeding disorders (such as hemophilia), or severe trauma including nonaccidental injury. Mild trauma such as from a fall does not cause persistent joint swelling, and trauma is rarely a cause of joint swelling unless there is an internal derangement seen in older, not younger, children. Children with hypermobility can develop transient joint effusions after exercise,⁵⁶ but this should not be long-lasting swelling. Lyme disease (in an endemic area) can cause recurrent monoarticular arthritis (typically involving the knee and often popliteal cysts), usually for less than 6 weeks. As described earlier, ALL may present with bone and joint pain and swelling, often monoarticular. If there is any concern of malignancy or infection, a complete blood count with manual differential and peripheral smear is crucial and bone marrow examination should be performed if indicated.

A common initial response by general pediatricians when evaluating children with joint pain or swelling is to believe the problem is mechanical. However, in young children and toddlers, orthopedic problems such as meniscal tears or ligamentous injury are exceedingly rare because of

the nature of pediatric musculoskeletal development and anatomy. In general, ligaments and tendons are stronger than growing bone in children, and the bone-ligament or bone-tendon junction is the weakest link. Therefore fractures are more common in children than adults, but nonaccidental trauma should always be considered, especially in children younger than 3 years.

Treatment

The treatment strategies for extended versus persistent oligoarticular JIA differ in both the approach to therapy and the intensity of escalating treatment on the basis of the number of joints at risk for significant damage. For *extended oligoarticular JIA*, treatment approaches are similar to RF-positive or RF-negative polyarticular JIA because these subtypes all have polyarticular involvement (see [Figure 107-1](#)). Treatment of *persistent oligoarticular JIA* is usually approached in a stepwise fashion ([Figure 107-2](#)). For these patients with a history of arthritis in four or fewer joints, the initial treatment is an NSAID, with or without an adjunctive IAS, followed by MTX if there is an inadequate response to one or more IASs. Initiation of MTX was recommended in the ACR guidelines for JIA as initial treatment for children with oligoarticular JIA with high disease activity and poor prognostic features, defined as involvement of hip, cervical spine, ankle or wrist, high inflammatory markers, or radiologic changes.⁹ Partial or complete remission on MTX can be induced in 60% to 70% with extended oligoarticular JIA.^{15,57,58} TNF inhibition should be considered in resistant cases, often in combination with MTX.

Concurrent sulfasalazine and hydroxychloroquine have been used with variable success. Sulfasalazine is more typically used with HLA-B27-associated arthritis and ERA.

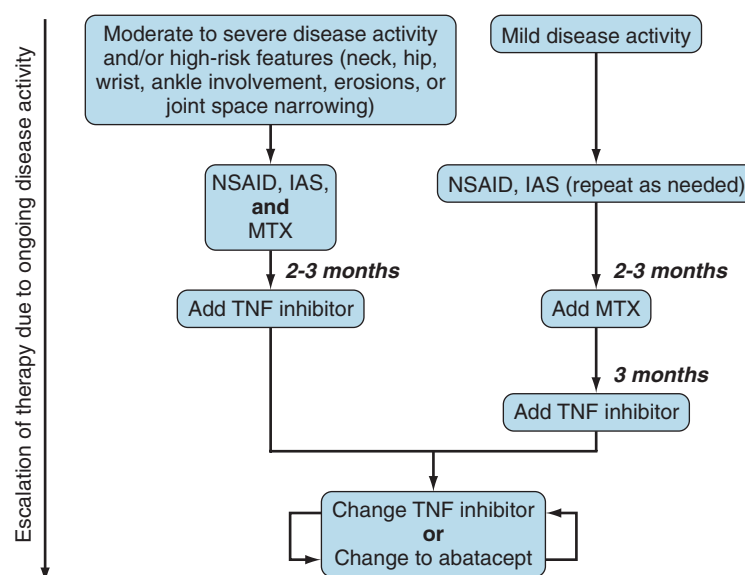

Figure 107-2 Persistent oligoarticular juvenile idiopathic arthritis (JIA) treatment algorithm including oligoarticular course psoriatic JIA. The treatment goal is remission of disease activity and is stratified by severity of disease. More disease activity or high-risk features should prompt disease-modifying antirheumatic drug use as initial therapy, whereas nonsteroidal anti-inflammatory drug (NSAID) monotherapy could be used initially for 2 to 3 months. If NSAID monotherapy is ineffective, therapy should be escalated. IAS, intra-articular steroid; MTX, methotrexate; TNF, tumor necrosis factor.

Special Considerations: Knee Monoarthritis

Because knee monoarthritis is the most common presentation of oligoarticular JIA, specific management is discussed here. The two treatments to be considered are NSAIDs and IASs, with evidence that IASs may be more effective even though most pediatric rheumatologists use NSAIDs before IASs.⁵⁹ An initial trial of NSAIDs may be conducted with the hopes of avoiding IASs in some patients, but the risk of IASs must be weighed against the cost of continued active arthritis. Choosing among treatment strategies involves a tradeoff between several different outcomes including duration of active arthritis, potential for long-term complications, adverse effects of therapies, discomfort of daily medications or potentially painful procedures and anesthesia, as well as parental preferences. Synovectomy is not indicated in oligoarticular JIA.

Outcome

Long-term studies of adults treated before the use of biologic agents have shown that up to 50% of adults who had oligoarticular JIA may have ongoing active disease or functional problems in adulthood,⁶⁰ and the rate of remission after 6 to 10 years from onset of disease ranges only from 23% to 47%.^{51,61} Ongoing disease activity and extension of joint involvement is related to a poor outcome and radiographic damage,⁶² and therefore emphasis on control of disease activity is critical. Morbidity from long-term inflammation can cause problems as well such as leg-length discrepancy with knee arthritis, muscle atrophy, bony overgrowth, and joint contractions (Figure 107-3), as well as other growth abnormalities such as micrognathia.

Figure 107-3 Radiograph of a young girl with oligoarticular juvenile idiopathic arthritis involving the right knee, demonstrating bony hypertrophy of the affected knee, with leg-length discrepancy and flexion contracture.

Patients with persistent oligoarthritis generally have the best outcome with 68% of patients achieving clinical remission off medication.^{43,51} Patients with an extended oligoarticular JIA have higher cumulative duration of active arthritis,⁴³ more erosive disease, and a higher risk of chronic disability.⁵¹ Only 31% of children with extended oligoarticular JIA achieved remission after discontinuing their medication.⁴³ Relapses occur, and within 2 years after clinical remission off medication, flares occurred in 47% of patients with persistent oligoarthritis and 67% of patients with extended oligoarthritis.⁴³ Diligence regarding ophthalmologic screening for asymptomatic uveitis needs to continue as described in “Uveitis.”

UVEITIS

Clinical Manifestations and Diagnostic Features

Chronic anterior uveitis, defined as inflammation involving the anterior uveal tract including the iris and ciliary body, is the most frequent extra-articular manifestation of JIA. Uveitis is most common in oligoarticular JIA and RF-negative polyarticular JIA, with a prevalence ranging from 17% to 26% and 4% to 25%, respectively. It is rare in RF-positive polyarticular JIA and sJIA.¹⁰ Risk factors for uveitis include ANA positivity, being younger than 6 years of age at JIA onset, female sex, and oligoarticular subtype.⁶³ These risk factors of developing uveitis are larger influences in girls but not boys.⁶⁴ The interval from diagnosis of JIA to the development of uveitis is longer the younger the age at onset of JIA, especially in ANA-positive patients.⁶⁴ Overall, uveitis is observed in 30% of ANA-positive patients with JIA.⁶⁵

Chronic anterior uveitis is typically nongranulomatous and asymptomatic at onset, and if unrecognized it can lead to serious visual deficits. Because of its insidious onset, regularly scheduled screening by an experienced ophthalmologist with slit lamp examination is required for early diagnosis and treatment. Newly diagnosed patients are ideally screened within 6 weeks of diagnosis⁶⁶ because in 5% of cases, uveitis occurs before diagnosis of JIA.⁶⁷ The highest risk period for uveitis development is the first 4 years after arthritis onset, although the risk is never completely eliminated.⁶⁷ The frequency of ophthalmologic screening according to the American Academy of Pediatrics guidelines is determined by the degree of risk such as ANA status, age of JIA onset, and duration of disease shown in Table 107-3.⁶⁷ In children with HLA-B27-related disease, anterior uveitis occurs in 10% to 15% but is usually highly symptomatic and therefore does not require routine screening.⁶³ The severity of chronic anterior uveitis associated with JIA is unrelated to the severity of the underlying joint disease, and the clinical course of the uveitis and arthritis may not parallel one another. Disease is eventually bilateral in nearly two-thirds of patients, but both eyes are not always inflamed at the same time.⁶⁸

Treatment

Differential Diagnosis

When evaluating the etiology of uveitis, it is important to consider infectious causes, such as tuberculosis,

toxoplasmosis, cytomegalovirus, herpes simplex virus, syphilis, human immunodeficiency virus, Lyme disease, cat scratch disease, and fungus. Uveitis can be confined primarily to the eye or occur secondary to a systemic illness, such as in Behçet's disease, sarcoidosis, autoinflammatory syndromes, multiple sclerosis, TINU (tubulointerstitial nephritis and uveitis syndrome), and Vogt-Koyanagi-Harada syndrome. Although the cause of uveitis often remains idiopathic, it is important to not miss a malignancy such as lymphoma or retinoblastoma.⁶³

Uveitis is initially treated with topical corticosteroids and mydriatics, although in approximately 30% of patients the uveitis remains active even with topical or local treatment with subtenon corticosteroid injections, and immunosuppressive medications are indicated to attempt to aggressively control the inflammation and prevent poor visual outcomes. Although there are no prospective randomized controlled studies on the use of immunosuppressive medications in children with uveitis, several observational studies suggest the effectiveness of these treatments. MTX, either oral or parenteral, is usually the first choice of treatment and is also used as a steroid-sparing agent.⁶⁹⁻⁷¹ Other effective immunosuppressives include mycophenolate mofetil⁷² and azathioprine, while cyclosporine has limited value.⁷³ Treatment of uveitis requires close collaboration between the affected child's rheumatologist and ophthalmologist.

In cases of refractory inflammation, biologic agents should be considered. TNF inhibitors are the most commonly used, specifically infliximab and adalimumab, which appear to be more effective than etanercept.⁷⁴⁻⁸¹ The dosing range and frequency of infliximab varies widely when used for uveitis, and up to 10 mg/kg/month are often required for control and should be used with MTX to prevent development of anti-infliximab antibodies. Adalimumab is given 20 to 40 mg subcutaneously every 2 weeks, and when ineffective, it can be administered weekly.⁷⁸ A case series reported remission with the administration of abatacept 10 mg/kg intravenously monthly in six of seven patients refractory to immunosuppressives and TNF inhibition.⁸² High-dose intravenous daclizumab, a humanized monoclonal antibody against IL-2 receptor, has been reported to be effective but is no longer available in the United States.⁸³

In the past, ophthalmologists were concerned about primary placement of intraocular lens in JIA patients with history of uveitis with subsequent formation of cataracts.⁸⁴ Now, with the more widespread practice of strict control of uveitis, good visual outcomes with cataract surgery and intraocular lens placement can be achieved using aggressive systemic immunomodulatory therapy perioperatively.⁸⁵ The general expert opinion among uveitis specialists is to try to taper immunomodulatory therapy after 12 to 24 months of quiescence of uveitis; however, this has not been studied.⁸⁶

Outcome

Complications resulting from uveitis include posterior synechiae, cataract, band keratopathy, glaucoma, papillitis, or cystoid macular edema. Posterior synechiae (fibrous bands adhering the iris to the lens, Figure 107-4) result in a distorted papillary border. Band keratopathy (a layer of calcium deposited in Bowman's membrane of the cornea), is not

Figure 107-4 Chronic anterior uveitis associated with oligoarticular and polyarticular rheumatoid factor–negative juvenile idiopathic arthritis, demonstrating posterior synechiae and absence of significant sclera inflammation.

uncommon. Cataracts and glaucoma may develop as a complication of the uveitis or its treatment, so chronic monotherapy with topical corticosteroids should be avoided.

The reported rate of visual loss due to JIA-related uveitis has decreased from 22% to 66% in studies before 1990 to 3% to 25% in newer studies, suggesting that newer and more aggressive approaches are effective.⁸⁷ Ongoing active intraocular inflammation with greater than or equal to 0.5+ cells was associated with increased risk of visual impairment and blindness.

Prognostic factors in JIA-associated uveitis are not clearly identified, and the results of the studies are often controversial. Different studies have revealed the following as potential factors associated with poor prognosis: short intervals between the diagnosis of arthritis and uveitis,⁸⁸⁻⁹⁰ severity of uveitis at first examination,^{91,92} signs of anterior chamber involvement (cells and flare),⁹² and male gender.^{89,93}

JUVENILE PSORIATIC ARTHRITIS

Clinical Manifestations and Diagnostic Features

Juvenile psoriatic arthritis (JPsA) was initially defined as juvenile-onset arthritis associated with psoriasis occurring at some point during the disease course. This definition has been expanded to include not only patients with overt psoriatic lesions but also arthritis who only have nail abnormalities or a first-degree relative with overt psoriasis.^{94,95} JPsA represents 2% to 15% of all JIA with slight female preponderance and a bimodal pattern of onset (2 to 4 years and 7 to 10 years).^{94,96,97} The psoriasis typically occurs within

2 years of the onset of arthritis, and for the majority of children the skin symptoms follow the arthritis symptoms.⁹⁸ Up to 80% of children have a classic psoriatic vulgaris or plaque psoriasis characterized by well-demarcated erythematous scaly lesions occurring over extensor surfaces (elbows and knees), scalp, and trunk.⁹⁸⁻¹⁰⁰ However, in small children younger than the age of 2, the most common finding is psoriatic diaper rash.¹⁰⁰ Additional areas that should be evaluated include the hairline behind the ears, the navel, the groin region, and superior to the gluteal cleft.⁹⁸

Because JPsA shares similar manifestations with multiple subtypes of juvenile arthritis, there is not one specific articular presentation. Patterns of joint involvement can be similar to both oligoarticular or polyarticular JIA with 60% to 70% of JPsA patients having an oligoarticular onset (<5 joints).¹⁰¹ There were no differences in ANA or HLA-B27 positivity, or frequency of uveitis between oligoarticular JIA and JPsA with fewer than 5 joints at onset, although dactylitis was more frequent, reported in 15% to 37% of JPsA.^{54,94,102} When JPsA subjects who had a polyarticular type course were compared with polyarticular JIA subjects, there was also no difference seen in ANA positivity, HLA-B27 positivity, and dactylitis. JPsA is associated with subacute anterior uveitis and ANA positivity in 15% to 20% of children with JPsA.¹⁰² A recent study of childhood psoriatic arthritis argued for two distinct subpopulations: (1) a younger group (median age, 2.7 years), ANA positive, with a female preponderance, all of whom had dactylitis and more persistent disease, and (2) an older group (median age 9.5 years), more likely to be oligoarticular, have axial disease and enthesitis, and have higher remission rates.⁹⁴

Children with psoriatic arthritis may have mild elevated acute-phase reactants (ESR, C-reactive protein [CRP], and platelets) and a mild anemia of chronic disease. However, up to one-third have no laboratory evidence of inflammation. Serologies and HLA associations are noted earlier.

Treatment

To date there have been no controlled studies examining the efficacy of antirheumatic medications in JPsA. A recent study compared treatment regimens of JPsA patients versus oligoarticular and polyarticular JIA patients and found no difference in use of NSAIDs, MTX, and TNF inhibitors.¹⁰² In general, the treatment of JPsA should follow the treatment approaches for oligoarticular or RF-negative polyarticular JIA (see Figures 107-1 and 107-2) depending on the patient's pattern of joint involvement. MTX is of benefit for both the skin psoriasis and arthritis and, when used in children, is recommended as a single weekly dose rather than split doses.⁹⁹ In children with more aggressive disease, TNF inhibitors (which have also been successful in treating psoriasis) are indicated and may significantly limit bony destruction.^{100,103,104} Regular screening for uveitis is required, especially in ANA-positive patients with both oligoarticular and polyarticular courses, with monitoring and management as described later in "Uveitis."

Outcome

Because of the heterogeneity in the patterns of arthritis in JPsA, the outcomes are variable and tend to track with the

pattern of joint involvement. Although in one study erosions were less common in JPsA compared with polyarticular JIA (23% vs. 46%, respectively), there appears to be more persistent disease activity and more evidence of physical limitations and ongoing disease activity continuing into adulthood in patients with JPsA compared with oligoarticular and polyarticular JIA patients.^{95,105} The uveitis of psoriatic arthritis, like that of oligoarticular disease, can lead to blindness if untreated.

ENTHESITIS-RELATED ARTHRITIS/ JUVENILE SPONDYLOARTHROPATHY

Clinical Manifestations and Diagnostic Features

The current ILAR category of ERA is a spectrum that includes spondyloarthropathies, juvenile ankylosing spondylitis, and SEA (spondylitis enthesitis and arthritis). ERA accounts for about 20% of JIA in one U.S. study,⁴⁷ but previous classification schemas have included JPsA within spondyloarthropathies resulting in variability in incidence and prevalence data.¹⁰⁶ In some cases, patients are first diagnosed as oligoarticular JIA, but characteristics of ERA later evolve. ERA occurs after age 6 and is more common in boys (male-to-female ratio of 7:1), although it may be under-recognized in symptomatic girls who can have milder disease with less axial skeleton involvement.¹⁰⁷

The typical feature of ERA is the presence of enthesitis, or inflammation of the tendons and ligaments where they attach to bone (or enthesis). It is an early manifestation and occurs more frequently in children than in adult-onset ankylosing spondylitis (AS).⁹⁸ The typical enthesitis sites are around the patella (at the 2, 6, and 10 o'clock positions); Achilles' tendon; plantar fascia insertions into the calcaneus and metatarsal heads, greater trochanter, tibial tuberosity, and the base of the fifth metatarsal. Children may report vague buttock pain, groin pain, or heel pain, and a classic finding is of tarsitis with inflammation of the subtalar joint and surrounding tendon sheaths. At onset spinal symptoms are rare, but a subgroup of children with ERA will progress to features more typical of adult AS with SI joint and spinal inflammation during adolescence. This progression is more likely in boys who are HLA-B27 positive and have spinal or sacroiliac pain within 1 year of diagnosis.¹⁰⁸ The modified Schober's test can be used to evaluate lower lumbar flexibility with a change less than 6 cm being abnormal.¹⁰⁹ Because thoracic excursion varies greatly in a growing child, only performing sequential measurements are helpful. In the adolescent, any thoracic excursion less than 5 cm should be regarded as abnormal.⁹⁸

ERA is associated with an acute anterior uveitis (AAU) in 6% to 27% of children, which typically presents as an acutely red, painful eye that needs immediate medical attention to avoid blindness.^{98,110,111} Cardiovascular disease, although uncommon, can be severe in patients with ERA that has evolved into juvenile ankylosing spondylitis, with inflammatory aortic regurgitation reported in up to 10% of patients.¹¹² Restrictive pulmonary disease has been seen in juvenile spondyloarthritis without clinical or radiologic findings.

Reactive arthritis is categorized under ERA, following infection with organisms from the gastrointestinal tract

(e.g., *Salmonella*, *Shigella*, *Yersinia*, *Campylobacter*, *Clostridium difficile*) or genitourinary tract (i.e., *Chlamydia* or *Ureaplasma*) without actual infection in the joint tissues. Usually self-limited, the arthritis can persist and transform into a more chronic arthropathy.¹¹³ In addition to the arthritis, urethritis and uveitis have been documented in children to complete the classic triad for reactive arthritis. The clinical infection usually precedes the arthritis, enthesitis, or extra-articular disease by 1 to 4 weeks. Arthritis associated with IBD (Crohn's disease or ulcerative colitis) is seen in children, and two distinct patterns of joint involvement are noted: (1) peripheral arthritis and (2) sacroiliitis and spondylitis, with the former more common than the latter. Additional clinical manifestations unique to arthritis associated with IBD include clubbing, periostitis, erythema nodosum, pyoderma gangrenosum, osteoporosis, and rarely hypertrophic osteoarthropathy. The peripheral arthritis activity has been shown to correlate with gut disease activity unlike the SI joint activity, which tends not to correlate.¹⁰⁹

Compared with adults, in whom radiologic evidence of sacroiliitis is the diagnostic hallmark of ankylosing spondylitis, radiologic evaluation in children with ERA is less often diagnostic because sacroiliitis is rare as a presenting symptom. Magnetic resonance imaging (MRI) with contrast is being increasingly used to detect evidence of acute sacroiliitis without chronic changes in children. MRI has also been used to evaluate enthesitis.¹¹⁴ HLA-B27 is present in 80% to 90% of cases depending on ethnicity. The ESR may be mildly or markedly raised, and there may be a mild anemia, but these should also raise the suspicion that the child may have subclinical IBD. RF is negative, and ANA may be positive.

Differential Diagnosis

Children with true infectious arthritides (viral, rheumatic fever, poststreptococcal, Lyme) can present with similar manifestations as ERA patients. More benign entities such as toxic synovitis and benign limb pains of childhood (growing pains), as well as more concerning entities such as malignancies and solid tumors, should be considered. Orthopedic diagnoses such as Legg-Calvé-Perthes disease, slipped capital femoral epiphyses disease, and Osgood-Schlatter disease and less common rheumatologic diseases such as SAPHO (synovitis, acne, pustulosis, hyperostosis, and osteomyelitis), Kawasaki's syndrome, and vasculitis can share similar articular and extra-articular manifestations with ERA. Lastly, children with widespread amplified musculoskeletal pain may have tender entheses that can be mistaken for enthesitis.

Treatment

Treatment of ERA ranges from NSAIDs to DMARDs with the use of biologics in the most aggressive cases. To date there have been few randomized controlled trials in this population. One study of sulfasalazine showed no significant effects in juvenile spondyloarthropathy, whereas another showed good response in oligoarticular- and polyarticular-onset JIA patients.^{115,116} Most respond well to intra-articular corticosteroid injections, but many may need a DMARD. For severe symptoms or evidence of potential joint damage

(such as erosive sacroiliitis), the use of TNF inhibitors has been effective on the basis of small pediatric studies.^{117,118}

Outcome

Long-term outcome of ERA is unknown, but a proportion of these children may progress to the adult form of AS. Predictors of sacroiliitis were HLA-B27 positivity, absence of DPB1*02, hip joint involvement within the first 6 months, and disease onset after age 8 years.¹¹⁹ When compared with adult-onset ankylosing spondylitis, juvenile-onset ankylosing spondylitis had less severe axial involvement but worse hip involvement, and in some studies, worse functional impairment.^{120,121} The probability of remission remains low with remission rates reported ranging from 17% to 44%. Predictors for failure to achieve remission include family history of AS in first-degree relative, female sex, younger age at disease onset, arthritis in ankle joint within 6 months of disease onset, and HLA-DRB1*08.¹²² Minden and colleagues⁵⁰ showed that if ERA persisted for more than 5 years, the chance of remission was only 17%.

SYSTEMIC JUVENILE IDIOPATHIC ARTHRITIS

Clinical Manifestations and Diagnostic Features

sJIA, which makes up 10% of all JIA, has unique characteristics that include fever, specific rash, and significantly elevated inflammatory markers in addition to arthritis. Recent research has identified biologic differences between sJIA and the other subcategories including prominent involvement of components of the innate immune system (in particular, inflammatory cytokines IL-1, IL-6, IL-18, neutrophils, and monocytes/macrophages), suggesting that sJIA may be in the autoinflammatory disease spectrum.¹²³

sJIA occurs at any age with a tendency toward younger than 5 years peaking around 2 years of age.^{124,125} Rarely it occurs in adults and is called adult-onset Still's disease. The gender predilection has stayed neutral, and some studies have suggested that sJIA may be relatively more frequent in Asian countries.¹²⁵ The systemic features of this disease are striking and are always present at onset, often predominating the clinical presentation. The arthritis may not be clinically present at onset, although arthralgias and myalgias are almost universally present at onset.⁹⁸ The fever is typically spiking in character with a peak of at least 39° C daily, occurring once or twice a day. Interestingly, the temperatures can become subnormal between fevers. The child is usually unwell and irritable during the fever but often recovers in between. In 80% of patients, the fevers are accompanied by an evanescent, migratory, salmon pink, and sometimes urticarial macular rash (Figure 107-5).¹²⁴ The rash typically spares the face and can occur without specific pattern on any part of the trunk or extremities. It can be subtle and scattered or diffuse and almost confluent. A helpful diagnostic feature is that the rash can be elicited by the Koebner phenomenon in which rubbing or scratching the skin elicits the rash.

Other systemic features include lymphadenopathy, hepatosplenomegaly, serositis (pleural/pericardial involvement/

Figure 107-5 Typical rash of systemic juvenile idiopathic arthritis, with small 1- to 5-mm flat or slightly raised salmon pink macules.

abdominal pain), headaches, and sore throat. sJIA has the most common and severe cardiac presentations of all the subtypes of JIA. Pericarditis and pericardial effusions are the most common organ system manifestations, occurring in up to 10% of the presentations.¹²⁴ A serious life-threatening systemic manifestation called *macrophage activation syndrome* (MAS) is discussed in more detail later. The arthritis in sJIA can be varied from minimal to oligoarticular to polyarticular presentation¹²⁴ and typically does not correlate with the severity of the systemic manifestations.¹²⁶ Tenosynovitis and synovial cyst formation can also be seen. Although the systemic manifestations can be serious initially, the long-term morbidity is due to articular disease and adverse effects of medications, especially chronic corticosteroids.

There are no diagnostic tests for sJIA, but there are characteristic patterns of laboratory abnormalities including high inflammatory markers (CRP, ESR), significant leukocytosis with neutrophilia and bandemia, thrombocytosis, and anemia. Liver transaminases, aldolase, ferritin, fibrin split products, and coagulation screen may be abnormal in severe cases and can be signs of early or impending macrophage activation syndrome (MAS). ANA or other autoantibodies are rarely present. Inflammatory cytokine gene expression profiles have been shown to distinguish sJIA from other febrile inflammatory diseases seen in children and may lead to more specific tests in the future.¹²⁷

Differential Diagnosis

Due to the nonspecific nature of the characteristics of sJIA, the diagnosis can be difficult and should be approached as a diagnosis of exclusion. Infections, Kawasaki's syndrome, malignancy, and other autoimmune diseases can present with similar symptoms; therefore it is necessary to screen for infectious agents and neoplasia, especially leukemia and neuroblastoma with appropriate tests including cultures, bone marrow aspiration and biopsy, and urinary vanillylmandelic acids. Some physicians do these tests routinely because malignancies are often close mimics to the early stages of sJIA. The recurrent fever syndromes are often mistaken for sJIA, but the character of the fevers and the fixed rashes associated with these syndromes should alert

the clinician to a different diagnosis. Other childhood rheumatic diseases should be considered such as systemic lupus erythematosus, Behçet's syndrome, and others.

Special Considerations: Macrophage Activation Syndrome

About 10% of the sJIA patients will develop overt life-threatening MAS, and up to 30% will develop a milder form, which if inadequately treated could lead to full-blown MAS.¹²⁸⁻¹³⁰ MAS is a form of secondary or acquired hemophagocytic lymphohistiocytosis (HLH) seen within rheumatic disease. Two-thirds of the mortality seen in all patients with JIA are due to this entity.¹³¹ The main manifestations include unrelenting high fevers, hepatosplenomegaly, lymphadenopathy, severe cytopenias, liver dysfunction, central nervous system (CNS) involvement (seizures/coma), and coagulopathy (Table 107-4). The ferritin often exceeds 10,000 ng/mL, and coagulopathy can be impressive with elevated prothrombin and partial thrombin times, hypofibrinogenemia, petechiae, mucosal bleeding, epistaxis,

Table 107-4 Preliminary Diagnostic Guidelines for Macrophage Activation Syndrome (MAS) Complicating Systemic Juvenile Idiopathic Arthritis (sJIA)¹⁷⁹

Laboratory Criteria
Decreased platelet count ($\leq 262 \times 10^9/L$)
Elevated levels of aspartate aminotransferase (>59 U/L)
Decreased white blood cell count ($\leq 4 \times 10^9/L$)
Hypofibrinogenemia (≤ 2.5 g/L)
Clinical Criteria
Central nervous system dysfunction (irritability, disorientation, lethargy, headache, seizures, coma)
Hemorrhages (purpura, easy bruising, mucosal bleeding)
Hepatomegaly (≥ 3 cm below the costal arch)
Histopathologic Criterion
Evidence of macrophage hemophagocytosis in the bone marrow aspirate
Diagnostic Rule
The diagnosis of MAS requires the presence of any 2 or more laboratory criteria or of any 2 or 3 or more clinical and/or laboratory criteria. A bone marrow aspirate for the demonstration of hemophagocytosis may be required only in doubtful cases.
Recommendations
The aforementioned criteria are of value only in patients with active sJIA. The thresholds of laboratory criteria are provided by way of example only.
Comments
The clinical criteria are probably more useful as classification criteria rather than as diagnostic criteria because they often occur late in the course of MAS and therefore may be of limited value for the early suspicion of the syndrome.
Other abnormal clinical features in sJIA-associated MAS, not aforementioned, may include nonremitting high fever, splenomegaly, generalized lymphadenopathy, and paradoxical improvement of signs and symptoms of arthritis.
Other abnormal laboratory findings in sJIA-associated MAS, not aforementioned, may include anemia, erythrocyte sedimentation rate fall, elevated levels of alanine aminotransferase, increased bilirubin, presence of fibrin degradation products, elevated lactate dehydrogenase, hypertriglyceridemia, low sodium levels, decreased albumin, and hyperferritinemia.

and hematemesis. Often MAS is heralded by a decrease of the ESR, leukocyte and platelet counts, and liver dysfunction.¹³² Histologically, patients with MAS show expansion of well-differentiated macrophages exhibiting hemophagocytosis in the bone marrow, lymph nodes, and other organs such as the liver and lungs. There is no gender, age, or race predilection for MAS in sJIA.¹³² It often occurs during active systemic disease but has also been seen in the quiescence phase of the disease (no clinical symptoms but still on medications).¹³³ Triggers for MAS in sJIA include bacterial, fungal, and parasitic infections. Epstein-Barr virus, varicella, coxsackie, parvovirus B19, hepatitis A, *Salmonella*, and *Pneumocystis* infections have been implicated. Drugs have also been implicated including aspirin, NSAIDs, sulfasalazine, MTX, etanercept, anakinra, and gold salts. One must be cautious to quickly lay blame because many patients who are receiving these medications have active disease and may have been developing MAS despite the medications.^{132,134} Most of the time, the trigger is unknown. Poor natural killer cell cytolytic activity leading to low levels of perforin expression has been reported in sJIA, a unique finding compared with the other subtypes of JIA.^{128,132,135} Soluble IL-2R α receptors and soluble CD163 are increased severalfold in MAS.^{128,136}

Treatment

sJIA is an active area of research with increasing understanding of the autoinflammatory biology and the potential

therapeutic roles for targeted biologics. Therapies such as MTX and TNF inhibition are less helpful in sJIA compared with other forms of JIA.^{45,125,137,138} An approach to treating sJIA is shown in Figure 107-6, separating this complex disease into different severities and manifestations. This algorithm is consistent with the recently published ACR guidelines for JIA.⁹ Mild sJIA, defined as mild systemic symptoms without organ system involvement and synovitis, can be successfully treated with anti-inflammatory doses of NSAIDs. Certain NSAIDs are helpful for different aspects of the disease (e.g., indomethacin can be used for fever control and serositis symptoms). In addition, if there are only a few large joints involved, intra-articular steroid injections are an additional option.

In the more severe cases with persistent fevers, cardiopulmonary symptoms, significant anemia, and significantly elevated inflammatory markers, corticosteroids may be used, often given as pulsed intravenous high-dose methylprednisolone (30 mg/kg/dose) daily for 3 days in a row followed by tapering doses of oral prednisolone.¹³⁹ Increasingly, as shown in Figure 107-6, IL-1 or IL-6 inhibition is instituted to avoid steroid toxicity and in some recent studies is being used as initial therapy before corticosteroids.¹⁴⁰ Use of DMARDs and TNF inhibitors may be more helpful for more significant articular disease. TNF inhibition has been shown to be effective in some patients with sJIA, though to a lesser extent than in other types of JIA.¹³⁷ Similarly, MTX may be helpful in sJIA with prominence of articular symptoms over systemic features.⁹ Cyclosporine as

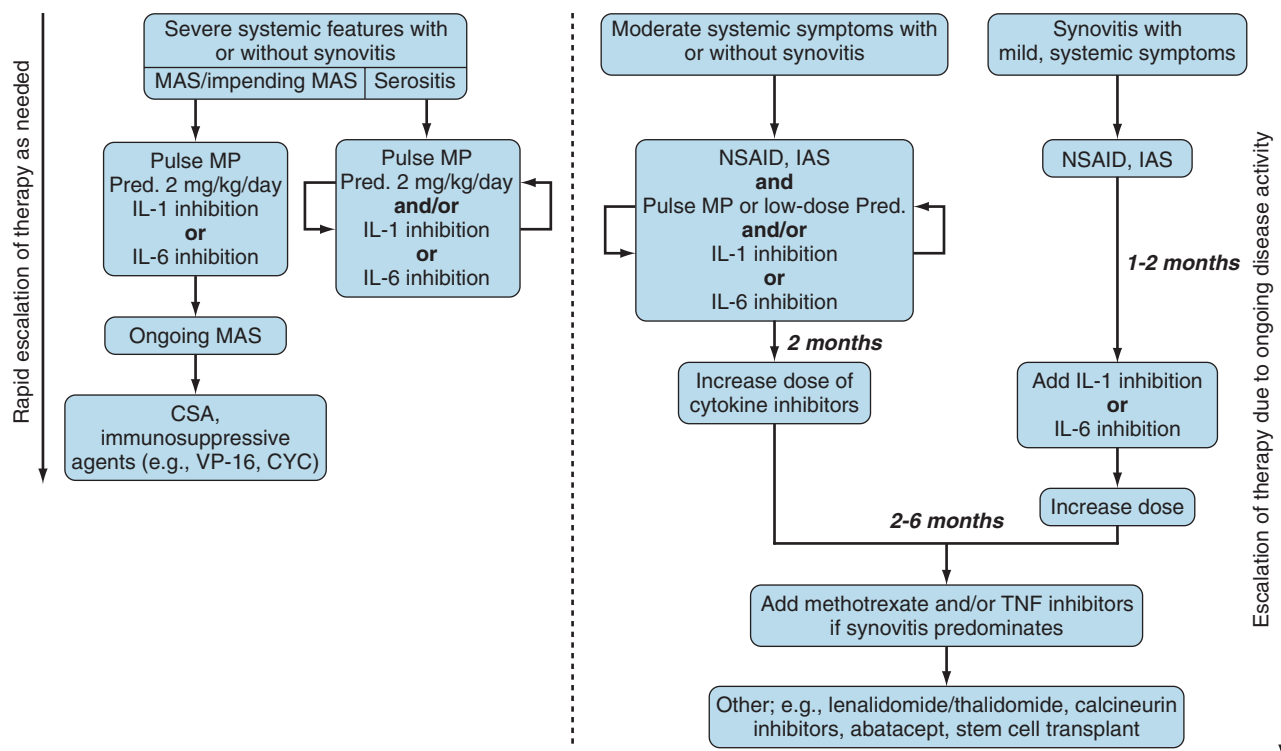

Figure 107-6 Systemic juvenile idiopathic arthritis treatment algorithm. The treatment goal is remission of disease activity, both systemic and articular, and is stratified by severity of disease. Algorithm is divided into severe systemic disease manifestations (macrophage activation syndrome [MAS], serositis) or synovitis with milder systemic disease. Currently there is significant variability in practice regarding using corticosteroid as initial systemic therapy or moving directly to inflammatory cytokine inhibitors. At the time of this writing, interleukin (IL)-1 inhibition and IL-6 inhibition are currently in trials, and more information is likely to be available in the future. CSA, cyclosporine A; CYC, cyclophosphamide; IAS, intra-articular steroid; MP, methylprednisolone; NSAID, nonsteroidal anti-inflammatory drug; Pred., prednisone; TNF, tumor necrosis factor.

well as monthly intravenous immunoglobulin have shown some benefit in systemic symptoms and can be used for steroid-sparing effects.^{140,141} Unfortunately, effectiveness of these DMARDS is much less than in other subtypes of JIA with cyclosporine less than MTX.

The newer biologics that block IL-6 and IL-1 signaling are promising according to the recent elucidations in the pathophysiology of sJIA, as well as recent clinical trials and studies. Initial reports on IL-1 blockade using anakinra showed rapid and sustained remission within a few days in sJIA patients with chronic disease activity resistant to conventional therapy.¹⁴² However, more recently reports have called into question the sustainability of the response using these medications.^{140,143,144} Newer IL-1 inhibitors such as rilonacept (currently being studied in a clinical trial, NCT00534495) and anti-IL-1 β monoclonal antibody (canakinumab) may shed more light on the effectiveness of these therapies and the biology of the responses. Two phase III placebo-controlled, double-blind trials using the IL-6 receptor antagonist tocilizumab showed significant improvement of ACR Pedi 30, 50, and 70 responses.^{145,146} In the TENDER trial, the tocilizumab dose for patients less than 30 kg was 12 mg/kg/dose and for greater than 30 kg was 8 mg/kg/dose every 2 weeks.¹⁴⁵

Thalidomide has also been reported to improve symptoms in refractory sJIA patients.¹⁴⁷ The teratogenic potential of thalidomide and its newer analogue lenalidomide limits the usefulness of these medications.¹⁴⁸

Abatacept has been used in sJIA patients who have failed previous treatments. In the open-label portion of a double-blind placebo-controlled trial of abatacept therapy in JIA patients, 24 of 37 (65%) of sJIA patients had an ACR Pedi 30 response. This was comparable with the other JIA subtypes evaluated in that study.³⁸

The 2010 ACR guidelines for JIA treatment divided sJIA treatment into two groups: active systemic features and active arthritis. But the guidelines did not include patients with MAS, impending MAS, or life-threatening manifestations (e.g., cardiac tamponade).⁹ The algorithm shown in Figure 107-6 incorporates some of the principles from the guidelines, expanding the area's severe systemic disease and MAS. One difference is that the guideline supports earlier use of methotrexate and TNF inhibition in patients with active sJIA with primarily articular manifestations.

The optimal treatment for MAS continues to be controversial. Therapy should be aggressive and usually starts with high-dose steroids and disease-modifying agents such as cyclosporine and IL-1 blockade.^{149,150} Almost 50% of patients in one study showed response to steroids alone.¹³⁴ A consensus treatment protocol for HLH has been published and uses a combination of VP-16 (etoposide), dexamethasone, with or without intrathecal methotrexate, followed by a maintenance with cyclosporine A.¹⁵¹ This protocol or parts of it have been used with MAS in sJIA patients with success.¹⁵² However, the new use of the powerful IL-1 and IL-6 inhibitors may preclude the need for the HLH approach with its potential serious bone marrow suppression.¹⁵¹

For the severe refractory cases, stem cell transplantation has been done. A recent review of the experience showed favorable response with more than 50% sustained drug-free remission. Early experience demonstrated cases of induction

of MAS during transplant conditioning and immediately post-transplant. This early morbidity has improved with less intense conditioning regimen.¹⁵³ A follow-up study reported that late relapses were noted with lower percentages for drug-free long-term outcome. The late relapses were often less severe and treated successfully with conventional drugs.¹⁵⁴⁻¹⁵⁶

Outcome

sJIA is heterogeneous in severity, disease course, and outcome. Studies of the natural history of sJIA before biologic therapies demonstrate that the course can be monocyclic, with remission within 2 to 4 years; relapsing, characterized by flares of systemic features with mild arthritis; or continuous with persistent destructive arthritis, often more prominent after the regression of systemic features.^{125,157} Patients with severe disease can have flares of extra-articular features at any time and may have active arthritis into adult life despite standard therapies.¹⁵⁷ Emerging evidence suggests that IL-1 and IL-6 inhibitors have permitted significant disease control with no or much lower doses of corticosteroids, which were one of the major causes of morbidity in sJIA in the past.

Predictors of poor articular outcome in sJIA include the systemic features 6 months after onset, thrombocytosis, and the presence of polyarthritis with hip involvement.^{125,158,159} The mortality rate for sJIA is still perceived to be higher than the mortality rate associated with other subtypes of JIA in clinical practice now, although no formal figures are available. As a result of the inadequate control of the disease with the available therapies, growth failure and osteoporosis are serious and lasting complications. The use of growth hormone (GH) is now more accepted with recent reviews outlining the safety of its use in sJIA. Growth hormone therapy can improve linear growth even during active phase of the disease, resulting in an ultimate higher final height.¹⁶⁰

Amyloidosis was previously a major cause of death in sJIA but is now less common, most likely due to the use of more aggressive therapy to better control inflammation. Recently MEFV mutations seen in familial Mediterranean fever have been identified in sJIA patients, and these patients were noted to have the most resistant disease.¹⁶¹ Pulmonary hypertension has also been reported in a few case reports and one case series.¹⁶²

IMAGING

Imaging is important in JIA to confirm the diagnosis; to exclude other diseases such as infection, malignancy, osteoid osteoma, or avascular necrosis; and to monitor therapy. Determining the presence of cartilage loss and erosions are complicated by the anatomically changing joints during the normal growth process. Because children have a large amount of cartilage in their joints, a significant amount of destruction can occur before erosions are identified on plain radiographs (Figure 107-7). Local growth disturbances can also be seen in children including bony overgrowth, particularly in the small joints of the hands and feet and in the knees, likely due to chronic hyperemia. Bony hypertrophy around the knee joints can lead to leg-length discrepancies,

Figure 107-7 Plain radiograph of a young child with active polyarticular juvenile idiopathic arthritis, demonstrating the challenge in evaluating joint damage in the growing child. Periarticular osteoporosis and early periostitis of the metacarpals are noted.

permanent gait disturbances, and secondary scoliosis (see Figure 107-3). In contrast, premature fusion of the epiphyses can lead to shortening of certain joints, most notably the TMJs, leading to micrognathia.¹⁶³⁻¹⁶⁵ Interestingly, the articular cartilage of growing children has been shown to have unique regenerative qualities and studies have shown that children with JIA can have improvement in their radiographic joint damage.¹⁶⁵

Plain radiographs in patients with JIA show soft tissue swelling as an early but nonspecific finding. The most common form of radiographic damage in JIA is joint space narrowing due to erosion, thinning, and loss of articular cartilage.^{163,165} Periarticular osteopenia due to hyperemia of inflamed joints is frequently seen. Erosions and ankylosis can be seen as late findings in radiographs.¹⁶³ Lastly, periostitis along the shafts of the phalanges, metacarpals, and metatarsals and calcifications from steroid joint injections can be seen. The trend toward early aggressive treatment to prevent erosive disease shifts the imaging need away from plain radiographs and toward other imaging modalities that are more sensitive in detecting early disease activity.¹⁶⁴ Therefore MRI and ultrasound (US) are becoming more popular.

US is reliable, safe, and relatively inexpensive but not as well standardized in children as in adults. It has been shown to be more sensitive than plain radiography in the detection of effusion, synovial thickening, and synovial cysts. In more experienced hands, cartilage thinning and bone erosions can also be seen. Inflammatory involvement of the hip, shoulder, and elbow is more frequently accurately detected by US compared with clinical examination.^{166,167} Color and power Doppler US can facilitate the evaluation of hyperemia and vascular abnormalities in affected joints and tendon involvement.¹⁶⁸

MRI is the most sensitive imaging modality currently available for detecting synovial inflammation; however, its use is limited by expense and the need for anesthesia in young children. With the use of contrast, accurate differentiation between active and inactive states can be established. Synovial enhancement and thickening can easily be seen,¹⁶⁹ and pannus volume measurements can be tracked.¹⁷⁰ MRI is the only technique available to visualize bone

marrow edema, which has been shown to be an important predictor of erosive joint damage in RA patients, but the connection is not established in JIA patients. For evaluating bony erosions, MRI was found to be the most sensitive imaging modality in wrists of JIA patients, revealing more than twice as many erosions compared with plain radiography and US.¹⁷¹ Pilot MRI grading scores of hip and knee disease activity and damage in JIA have been proposed but not validated.¹⁶⁴ A recent systematic review of the literature assessed that the overall quality of the reporting of methods in studies on the MRI assessment of JIA is heterogeneous and fair overall.¹⁷²

SPECIAL CONSIDERATIONS: REHABILITATION IN CHILDREN

PT and OT play a crucial role in JIA patients. PT and OT can consult for stretches, range-of-motion evaluation, joint protection, muscle building and strengthening, as well as endurance and graduated aerobic activity. Children who present late in the course of oligoarthritis may already have flexion contractures, which require splinting and serial casting. Serial casting is done two or three times a week for up to a month if necessary and is probably most effective when started just after joint injections. Some children with marked leg-length discrepancy (resulting from overgrowth of the affected knee) may require a shoe lift/raise. Strict limitations from physical education at school and sports are generally not encouraged because physical activity plays an important role in rehabilitation and therapy; however, impact sports should be limited in the presence of joint effusions or when there is a concern for joint instability (e.g., C1/C2 atlantoaxial subluxation). A modified physical education program and sports activities to the patients' own tolerance are recommended instead. Orthotics can be helpful in foot involvement in ERA, as well as other types of JIA.

Although there is a wide within-patient and between-patient variability, children with early-disease onset and a greater number of restricted joints have the highest risk of developing long-term functional physical disability.¹⁷³ In addition, health-related quality of life was significantly lower in patients with JIA than in healthy children, and patients with persistent oligoarthritis were less severely affected compared with the other JIA subcategories.¹⁷⁴ Total energy and activity-related energy expenditure, as well as physical activity levels, were significantly lower in JIA patients compared with controls, and only 23% of the JIA patients met the public health guidelines on physical activity compared with 66% in controls.¹⁷⁵

SUMMARY

The modern treatment of JIA has significantly decreased the long-term burden of disease but requires early recognition and diagnosis. It also requires aggressive treatment to extinguish disease activity and multidisciplinary approaches to maintain and improve function and quality of life. Pediatric rheumatologists have in their favor the remarkable capacity for childhood growth and development to allow repair and restoration of function, in contrast to adults with

inflammatory arthritis. The advent of new biologic therapies and rapid translation of basic research into therapeutic strategies and an increased willingness on the part of regulatory bodies to make new therapies available to children should combine to continue to improve the outlook for children with arthritis.

**KEY POINTS**

Pediatric systemic lupus erythematosus (SLE) accounts for 11% of patients referred to pediatric rheumatology clinics and approximately 20% of all cases of SLE.

Children with SLE appear to have more severe disease than adults, with an especially high incidence of renal involvement.

Thrombocytopenic purpura and autoimmune hemolytic anemia may be presenting manifestations of SLE in children.

With the use of aggressive treatment regimens, including intravenous cyclophosphamide and (presumably) mycophenolate mofetil, the prognosis for children with lupus nephritis has improved considerably, with greater than 90% survival and good renal function at 5 years.

Neonatal lupus, characterized by rash, fever, and other systemic manifestations, with or without congenital complete heart block, is caused by maternal anti-Ro antibodies in association with other factors, one of which is maternal HLA-DR3.

Inflammatory muscle disease in children almost always takes the form of juvenile dermatomyositis, with childhood polymyositis being very rare. Unlike in adults with dermatomyositis, an immune complex vasculitis is often present in childhood dermatomyositis and may be a major cause of morbidity and mortality. It has a predilection to involve the skin and the gastrointestinal tract.

Myositis is present in as many as 25% of children with systemic sclerosis and may be the presenting manifestation.

Localized scleroderma, including linear scleroderma and morphea, is three times more common than diffuse systemic sclerosis in children. In most cases, the disease remains localized and does not progress to diffuse disease.

Although the cause of Kawasaki disease is still unknown, treatment with intravenous IgG has been shown to improve mortality results by decreasing the number and severity of coronary artery aneurysms.

Henoch-Schönlein purpura, an IgA-mediated vasculitis, is the most common cause of vasculitis in children. It usually has a good prognosis, even in children with nephritis.

This chapter focuses on some of the most common systemic rheumatic diseases of childhood: pediatric systemic lupus erythematosus (SLE), juvenile dermatomyositis (JDM), scleroderma and its distinct subtypes, and the diseases in the spectrum of childhood vasculitis. Recent international collaborative efforts have substantially increased our

Pediatric Systemic Lupus Erythematosus, Dermatomyositis, Scleroderma, and Vasculitis

RONALD M. LAXER • SUSANNE M. BENSELER

understanding of these diseases and enabled us to recognize novel inflammatory diseases and their mimics.

SYSTEMIC LUPUS ERYTHEMATOSUS

Definition and Classification

Pediatric SLE (pSLE) is a chronic multisystem autoimmune disease with remitting, relapsing course and onset of symptoms before age 18 years, accounting for approximately 20% of all SLE.¹ This clinically heterogeneous disease is characterized by a distinct spectrum of autoantibodies including antinuclear antibody (ANA), double-stranded deoxyribonucleic acid (dsDNA), and antibodies against extractable nuclear antigens (ENAs). In genetically susceptible hosts B cell-mediated autoimmune processes lead to a variable combination and severity of clinical symptoms including antibody-mediated vasculitis, direct antibody binding to target cells, and thrombotic organ dysfunction.

The American College of Rheumatology (ACR) classification criteria for adults with SLE are commonly applied to children with pSLE.² The classification of neuropsychiatric SLE (NPSLE) in children and adolescents remains a challenge.^{3,4} The 1990 ACR NPSLE nomenclature and case definitions appear to have limited applicability for children in certain domains.⁵⁻⁷

Epidemiology

Pediatric SLE affects children and adolescents around the world.⁸⁻¹⁰ On average, 60% of patients develop pSLE after age 10, 35% between 5 and 10 years, and only 5% before age 5. In studies from Asia, the mean ages at diagnosis were reported to be 8.6 to 13.5 years.^{8,9} The incidence and prevalence of pSLE varies between populations. Similar to adults, SLE more commonly affects non-Caucasian populations.^{8,9,11} Overall, incidence rates of pSLE have been reported to be 0.28 to 0.48 per 100,000 children with prevalence rates of 6.3 to 24 per 100,000 depending on the ethnic background of the population.⁹ The prevalence of pSLE is consistently higher in girls than boys: Canadian and Taiwan studies estimated a factor of 6.^{12,13} Female predominance increases with age. This observation strongly supports the suggested role of female hormones.¹⁴ Although pSLE is less common than adult SLE, childhood onset was recently

found to be a strong, independent predictor of overall lupus mortality.¹⁵

Children with pSLE are likely to have relatives with SLE. The pattern of familial aggregation for siblings with SLE suggests a polygenic inheritance.¹⁶ In addition, pSLE patients often have asymptomatic relatives with evidence of autoantibodies.¹⁷

Causes

Genes

Enabled by large international collaborations, susceptibility genes have been identified suggesting a dysregulated immune phenotype in lupus patients partially overlapping with other autoimmune diseases.¹⁸ These include genetic variants in the cytokine interferon- α pathway and their functional impact,¹⁹ the contribution of signal transduction *STAT4* gene variations on lupus susceptibility,²⁰ and the association of the interleukin-1 receptor-associated kinase-1 (*IRAK1*), an X chromosome gene, and disease susceptibility in pSLE.²¹

Beyond the type of gene variant (mutation, polymorphisms), altered copy number variations reflecting “gene dose” and epigenetic modifications of key lupus genes are reported in pediatric lupus patients: Garcia-Ortiz demonstrated an association of the lupus gene Toll-like receptor 7 (*TLR7*) copy number variation with susceptibility to pSLE in Mexican populations.²² Drug-induced SLE and incomplete monozygotic twin concordance rates suggest an important role of epigenetic factors such as histone modification or altered DNA methylation in pSLE.²³ Finally, mitochondrial DNA polymorphisms may also be important in the pathogenesis of SLE.²⁴ Children with inherited complement deficiencies including C2, C4A/C4B, C1q, and C1s can present with pSLE.²⁵ These single gene defects are more commonly seen in familial cases of lupus.

Environment

Beyond genes and epigenetics, other potential contributing factors have been intensely studied in pSLE including environmental factors such as parental smoking²⁶ and organic dust exposure.²⁷ As a link between genetic and environmental factors, endogenous and external viruses are currently being studied in pSLE.²⁸ The presence of an interferon signature pattern had raised suspicion for a potential viral contribution and discovery of the genetic basis of chilblain lupus.²⁹ This focused the researchers’ attention to DNA repair of endogenous virus as a potential pathogenetic factor in pSLE.

Pathology

Similar to adult SLE, the inflammatory processes leading to organ dysfunction are heterogeneous between and within organs (see Chapter 79). Immunoglobulin deposition in small vessels such as glomerulus or lung capillaries, complement activation, antibody-binding to single cells, and microthrombotic or macrothrombotic vessel disease are the hallmarks of lupus. Hematologic manifestations of lupus are often related to direct antibody-binding and complement

activation.³⁰ In contrast, the histology of pediatric lupus nephritis is more variable and includes the distinct subtypes of mesangial, focal, or diffuse proliferative and membranous nephritis, which can coexist.³¹ Renal biopsies are required to distinguish subtypes and define treatment regimens. In children, severity of the glomerulonephritis on renal biopsy was shown to be associated with treatment choice and response and long-term outcome.³¹⁻³⁴ Confounding risk factors for severe lupus nephritis and adverse renal outcome include evidence of thrombotic microangiopathy, antiphospholipid antibodies, tubulointerstitial disease, hypertension, nephrotic syndrome, and access to health care.³¹⁻³⁵

Clinical Features

The clinical presentation of pSLE was reported in large series from many countries, allowing a better understanding of the clinical diversity, impact of ethnicity, confounding factors including infections, and access to health care^{8,11,36-47} (Table 108-1).

Systemic features including fever and fatigue are found in more than 90% of children at diagnosis of pSLE. Arthritis is the most frequently reported organ manifestation in pSLE. Typically pSLE arthritis is a nonerosive, painful polyarthritis. Mucocutaneous involvement includes the typical “butterfly” or malar rash, an erythematous rash in the malar distribution sparing the nasolabial folds (Figure 108-1). Diffuse hair loss is commonly seen in children with active disease. In addition, children with lupus can present with a photosensitive rash, exacerbated in sun-exposed areas including upper arms, neckline, and face; Raynaud’s phenomenon of fingers and toes; a vasculitic skin rash, which is often raised and painful affecting the fingers and toes; and oral and/or nasal ulcers. Oral ulcers are typically located on the hard palate and are painless (Figure 108-2). Uncommon skin manifestations include discoid lupus lesions, which heal with scarring.⁴⁸

Nephritis is the most common major organ manifestation and occurs in more than 50% of children with pSLE, most commonly at diagnosis. Children with lupus nephritis present with peripheral edema, proteinuria, active urine sediment, and hypertension. Focal or diffuse proliferative

Figure 108-1 Malar rash of a 14-year-old patient with pediatric systemic lupus erythematosus. The disease’s typical “butterfly” or malar rash is an erythematous rash in the malar distribution, which includes the cheeks and crosses the nasal bridge but spares the nasolabial folds.

glomerulonephritis accounts for more than 50% of all pediatric lupus nephritis in most series. Acute renal failure can occur in a third of children presenting with proliferative lupus nephritis.³³ Mesangial and membranous nephritis are less common and can occur in conjunction with

Figure 108-2 Oral ulcers in a 16-year-old girl with active pediatric systemic lupus erythematosus. Characteristic oral ulcers and hyperemia in children with lupus can be found on the hard palate. These ulcers are typically painless.

proliferative lupus nephritis. Posterior reversible encephalopathy (PRES) is an increasingly recognized central nervous system (CNS) complication of lupus nephritis and hypertension.⁴⁹

Neuropsychiatric disease affects about a quarter of children with pSLE. Headaches in conjunction with psychosis or cerebrovascular disease presenting as seizures or severe cognitive dysfunction are the most common clinical phenotypes. Isolated lupus headache is uncommon.⁷ Psychosis in pSLE is characterized by optic and acoustic hallucinations and visual distortions. Many patients have overlapping features of cognitive dysfunction, headaches, and mood disorder.⁵ Isolated mood disorders such as depression are uncommon in pSLE. CNS vasculitis in pSLE more commonly affects the small vessels. Angiography-positive disease and strokes are uncommon.⁷ Transverse myelitis is an uncommon, serious manifestation of pSLE.⁵⁰ Peripheral neuropathies are uncommon in children with lupus.

The diagnosis of NPSLE in children is based on clinical assessment including comprehensive neurocognitive testing,⁵¹ inflammatory markers, and neuroimaging. Children with neuropsychiatric disease commonly have

antiphospholipid antibodies, in particular anti- β_2 -glycoprotein I (anti- β_2 GPI).⁵² A positive lupus anticoagulant is often detectable in children with cerebrovascular disease including sinus vein thrombosis (SVT) and chorea. Neuroimaging demonstrates only subtle abnormalities in half of patients⁵ including the majority of children presenting with psychosis.

Hematologic disease is common in pSLE and affects a quarter of children. Treatment-refractory idiopathic thrombocytopenic purpura (ITP) or severe autoimmune hemolytic anemia can be the presenting features of pSLE. A positive ANA and older age were found to be risk factors of pSLE in ITP.⁵³ Serositis including pleuritis, pericarditis, and less commonly peritonitis affects about 20% of children with pSLE. Chest pain is the most common presenting feature. Inflammatory lung lesions including capillaritis and alveolar hemorrhage are uncommon. Although cardiomegaly due to pericarditis and arrhythmia/conduction anomaly occur frequently, myocarditis and coronary arteritis are serious yet uncommon lupus features in children.^{54,55} The most common gastrointestinal (GI) manifestation of pSLE is lupus hepatitis. Inflammatory bowel manifestations are rare. Overall atypical presentations can be found in up to a quarter of children ultimately diagnosed with pSLE and, when present, were found to correlate with poor outcome.⁵⁶ Endocrinopathies of pSLE include hypothyroidism or hyperthyroidism and diabetes mellitus.⁵⁷ Menstrual cycle disturbances and transient amenorrhea are common in girls with pSLE and may be associated with pituitary dysfunction or treatment with cyclophosphamide, leading to a decreased progesterone production.⁵⁸

Diagnosis and Diagnostic Tests

The diagnosis of pSLE is based on clinical findings, laboratory test results including inflammatory markers, complement levels, markers of organ involvement, and specific autoantibodies. Tissue biopsies and imaging studies can further support and/or classify pSLE subtypes. The presence of 4 of 11 ACR classification criteria was found to have a sensitivity of 96% and a specificity of 100%.² A careful evaluation of potential organ involvement of pSLE is mandatory. Characteristic abnormal laboratory markers of active pSLE may include a raised erythrocyte sedimentation rate (ESR), anemia, which may be Coombs positive and hemolytic, a low white blood count with predominant lymphopenia, low platelets, and low C3 and/or C4 complement levels. Paradoxically, the C-reactive protein (CRP) is normal in the vast majority of children with active lupus, except for those presenting with serositis or concurrent infections. An abnormal urinalysis including microscopic evidence of casts indicated renal involvement. Renal function impairment is best evaluated by serum creatinine, albumin, and urine protein-to-creatinine ratio. Lupus anticoagulant and specific lupus autoantibody testing including ANA, dsDNA, ENA, and antiphospholipid antibodies is mandatory. ANA is found in almost every child with pSLE, while dsDNA is detected in more than 80%.^{41,59} Novel antibodies have been proposed and require prospective validation in pSLE.⁶⁰ Children may have frank hypothyroidism or hyperthyroidism or solely raised titers of thyroid antibodies.⁴¹

Lipid abnormalities are increasingly recognized in children with pSLE.⁶¹ Dyslipidemia may contribute to a risk of premature arteriosclerosis in pSLE patients.^{62,63} Cytokines derived from adipocytes including leptin, adiponectin, and ghrelin were recently shown to correlate with disease activity in pSLE.⁶⁴ Markers of bone health and fracture risk have been extensively evaluated in children with pSLE.⁶⁵ A comprehensive assessment may include these markers in conjunction with bone density measurement.

The differential diagnosis of pSLE is wide and includes infections such as cytomegalovirus (CMV), Epstein-Barr virus, and tuberculosis, malignancies such as lymphomas, endocrinopathies, primary inflammatory or idiopathic organ diseases such as membranoproliferative nephritis, or idiopathic psychosis and pediatric autoimmune diseases including JDM, systemic sclerosis, Sjögren's syndrome, overlap syndromes, and polyarticular and systemic juvenile idiopathic arthritis.^{66,67} Children with a recent diagnosis of pSLE can present with concurrent infections such as CMV, which may confound the clinical presentation and response to therapy.⁶⁸ Uncommon infections may be present.⁶⁹ Macrophage activation syndrome (MAS, a secondary hemophagocytic lymphohistiocytosis [HLH] syndrome) is a newly recognized inflammatory emergency and can present in pSLE patients.⁷⁰ MAS has to be considered in a child with pSLE and unexplained fever and cytopenia, when associated with marked hyperferritinemia.

Treatment

The care for children with lupus, similar to other multiorgan rheumatic diseases, mandates a multidisciplinary approach of different subspecialty physicians including pediatric rheumatologists, nephrologists, psychiatrists, and adolescent medicine, allied health care specialists, social workers, and teachers.

Immunosuppression

The choice and dosing of immunosuppressive therapy regimen must be tailored to the extent and severity of the child's organ disease. A thorough diagnostic evaluation is mandatory before initiating therapy. Immunosuppressive treatment protocols are commonly adopted from adult trials and meta-analyses.⁷¹ Treatment response criteria for pSLE were recently developed and validated.⁷²

Corticosteroids are the mainstay of lupus therapy. The general approach for major organ disease includes initial high-dose treatment with 2 mg/kg prednisone equivalent in two to three divided doses followed by a slow taper. This includes treatment of proliferative lupus nephritis, neuropsychiatric lupus except for chorea and SVT, myocarditis, and lung disease. Pulse intravenous (IV) methylprednisolone is frequently used for emergent situations including acute psychosis, MAS, and myocarditis. Arthritis, serositis, nonproliferative lupus nephritis, and mucocutaneous disease may require smaller initial doses of corticosteroids. The efficacy of corticosteroids in pSLE is well established. However, the significant toxicity limits its long-term use at high doses. Short-term side effects include weight gain, sleep disturbances, emotional instability, increased hair growth, and impaired glucose metabolism. Long-term effects

include cataracts, growth arrest, vertebral fractures, and avascular necrosis.⁵⁷

Combination immunosuppressive regimens are commonly used in children with major organ involvement. Cyclophosphamide, mycophenolate mofetil (MMF), and azathioprine have been studied in observational cohorts of pSLE patients. IV cyclophosphamide was considered the gold standard for severe organ disease such as proliferative lupus nephritis and neuropsychiatric disease. In accordance to adult SLE protocols, cyclophosphamide is commonly used for induction over 6 months, followed by either azathioprine or MMF.⁷³ Induction therapy with MMF was found to be safe, well tolerated, and effective in a small cohort of renal and nonrenal pSLE patients.⁷⁴⁻⁷⁷ Complete renal remission is achieved in 40% to 50% of children at 6 months and 75% at 12 months.⁷⁸ Commonly reported side effects that led to discontinuation of MMF therapy included severe diarrhea and abdominal pain.⁷⁵ In children, optimal dosing may require pharmacokinetic evaluation on a stable dose.^{79,80} Efficacy and safety of MMF as maintenance drug is well established in pSLE.^{73,81,82} Induction therapy with azathioprine was found to be equally efficacious as cyclophosphamide in children with proliferative lupus nephritis and renal failure.³³ Azathioprine has a good efficacy and safety profile.⁸³ Routine monitoring of blood counts and liver function is required. Significant toxicity may occur in children with mutations in the gene encoding thiopurine methyltransferase or thiopurine S-methyltransferase (TPMT); however, the role of genotyping remains controversial.⁸⁴ Azathioprine is also used as a maintenance drug following induction with cyclophosphamide.⁷³

Dialysis is required in children with end-stage renal disease.³³ Plasmapheresis is indicated for specific disease manifestations such as thrombotic-thrombocytopenic purpura (TTP),⁸⁵ transverse myelitis, and steroid-resistant nephritis.⁸⁶ B cell depletion with the anti-CD20 antibody rituximab is the main biologic therapy currently used in pSLE.⁸⁷⁻⁹¹ It was shown to be effective as a single agent in hematologic disease and in addition to standard therapy in refractory, difficult-to-treat pSLE. The safety profile remains to be systematically studied in pSLE. Autologous stem cell transplantation is rarely performed in pSLE.⁹²

MAS therapy in pSLE may include IV immunoglobulin, IV methylprednisolone pulse therapy, cyclosporine, or even chemotherapy according to HLH protocol.⁹³

Antimalarials

Antimalarials are strongly recommended for children and adults with SLE.⁹⁴ On the basis of predominantly adult studies and meta-analysis, antimalarials are thought to decrease overall mortality and improve long-term outcome,⁹⁵ modify lipid profiles,⁹⁶ and control joint and skin disease, in particular discoid lupus lesions.^{97,98}

Adjunctive Therapy

Supportive medical therapies include angiotensin-converting inhibitors for renal protection and hypertension, contraception when applicable, organ dysfunction therapies including anticonvulsants and antipsychotic medication, and anticoagulation when applicable. High-factor

sunscreen for sunburn protection is important. Educational efforts have to include disease and treatment, medication side effects, infection risk, and impact on social life and school.

Vitamin D is known to be a strong factor of bone protection in pSLE.^{99,100} Sufficient vitamin D doses in addition to calcium intake and physical activity are required to maintain good bone health. More recently a novel role of vitamin D in maintaining immune homeostasis was recognized. This is supported by studies demonstrating an inverse correlation between vitamin D levels and disease activity,^{101,102} in particular in overweight children with pSLE.

Outcome

Lupus in children and adults is a relapsing/remitting disease. The burden of pSLE is complex to determine because many factors such as access to health care, individual patient characteristics, disease activity, confounding diseases such as infections, and responsiveness to treatment all contribute to overall mortality and morbidity.¹

The overall mortality as captured by standard mortality rate (SMR) for all SLE in the United States between 1992 and 2001 was 3.06 deaths per million inhabitants per year,¹⁰³ in Brazil between 1985 and 2004 it was 3.8 (2601 deaths, 90% female),¹⁰⁴ and in Denmark it was 4.6.¹⁰⁵ With improved therapies, mortality rates were shown to decrease in Canada (SMR, 10.1 in 1970-1977; 4.8 in 1978-1985, and 3.3 in 1986-1994).¹⁰⁶ When comparing childhood- with adult-onset SLE, childhood-onset SLE was found to be independently associated with an increased mortality risk (hazard ratio [HR], 3.1), as was low socioeconomic status measured by education (HR, 1.9), and end-stage renal disease (HR, 2.1).¹⁵

Young age at disease onset was repeatedly shown to be a predictor of adverse outcome.^{47,107} Children with pSLE in poor countries clearly have a higher mortality: In a small study from Nigeria the mortality was 30%.¹⁰⁸ The Latin American LUMINA cohort had an 81% survival at last follow-up, the recent 5-year patient survival rate in Iran was 82.5%,³² and in Canada it was 100%.^{41,109} Infections continue to be the main cause of death in developing countries with limited access to health care.^{34,110} Nephritis has been consistently identified as a predictor of poor outcome in pSLE. Histologic subtype of proliferative disease, evidence of disease relapse, certain ethnicities, and poor response to therapy were strong predictors of end-stage renal disease in pSLE.¹¹¹ Gibson demonstrated that treatment resistance portended a high risk of end-stage kidney disease and disproportionately affected African-American children with lupus nephritis.¹¹¹

Children with pSLE accrue disease- and treatment-related damage as captured in the domains of the Systemic Lupus International Collaborative Clinics (SLICC) Damage Index (see Chapter 80), constantly adding to the overall disease burden.^{1,57} Osteoporosis, cataracts, and osteonecrosis/avascular necrosis (AVN) are the leading domains of damage accrual. Individual patient characteristics, disease activity, corticosteroid therapy, calcium/vitamin D deficiency, and immobility contribute to impaired bone health in pSLE.^{112,113} AVN occurs in 6% to 10% of pSLE patients overall and is associated with corticosteroid therapy.⁴¹ Nakamura¹¹⁴

recently observed the complete absence of AVN in children younger than 14 years of age and suggested that age at the time of the initial corticosteroid therapy affects AVN occurrence. Neurocognitive deficits secondary to disease and treatment are increasingly recognized and significantly affect school performance and overall health-related quality of life.^{115,116} Early cardiovascular events including myocardial infarctions and strokes have become a major cause of morbidity and mortality.¹

Drug-Induced Lupus Erythematosus

Several medications can cause systemic and subacute or chronic cutaneous lupus phenotypes in children.¹¹⁷ The cutaneous manifestations of systemic drug-induced lupus (DIL) include malar rash, purpura, erythema nodosum, urticaria, and photosensitivity. Systemic symptoms include arthritis, oral ulcers, pleuritis, hematologic manifestations, and less commonly renal disease. Characteristic laboratory findings of DIL are positive ANA and antihistone antibodies. Drugs implicated are minocycline, anticonvulsive drugs, hydralazine, procainamide, and isoniazid.¹¹⁸

Management of drug-induced lupus is based on the withdrawal of the offending drug. Topical and/or systemic corticosteroids and other immunosuppressive agents may be required in resistant cases.

Neonatal Lupus Erythematosus

Neonatal lupus erythematosus (NLE) is an acquired disease of the newborn caused by placental transfer of maternal anti-SSA/Ro and anti-SSB/La IgG antibodies. These can be present in mothers with SLE, Sjögren's syndrome, and other autoimmune connective disorders, as well as clinically healthy women. Antibody transfer can lead to inflammation of the cardiac conducting system and subsequent fibrosis resulting in congenital heart block (CHB), which may be detected as early as 20 weeks of gestation. A prolonged PR interval is the first electrocardiographic sign of conduction system abnormality in NLE. The degree of heart block can vary, and rapid clinical progression from normal sinus rhythm to complete CHB over 2 weeks may be observed, causing life-threatening cardiomyopathy and fetal hydrops in the most severe cases. Isolated endocardial fibroelastosis can be found in some infants.¹¹⁹ Interestingly, infants with prenatal exposure to high-titer anti-SSB/La antibody levels are more likely to have noncardiac features of NLE, whereas cardiac disease tends to be associated with moderate or high maternal anti-SSA/Ro levels, independent of anti-SSB/La titers in CHB.¹²⁰ The overall risk of CHB in anti-SSA/Ro-positive women is estimated to be 2% to 5%,¹²⁰ but this risk may be increased by 10-fold in women with a previous child with CHB.¹²¹ A recent study suggests an overall recurrence rate of cardiac NLE of 17%, independent of maternal health, antenatal use of steroids, antibody status, severity of cardiac disease in the first affected child, or sex of the subsequent child.¹²²

In addition to heart block, newborns with NLE can present with a characteristic NLE rash, hepatic dysfunction, and hematologic abnormalities including significant thrombocytopenia. Typically the NLE rash is located around the eyes but may present elsewhere on the body.¹²³

Hepatobiliary disease can have three distinct presentations: (1) transient conjugated hyperbilirubinemia with mildly raised liver function tests (LFTs) in the first weeks of life; (2) mild elevations of LFTs at 2 to 3 months of life; and (3) severe liver failure during gestation or in the neonatal period.¹²⁴ NLE neurologic involvement can include magnetic resonance imaging (MRI) findings of nonspecific white matter changes and calcification of the basal ganglia. NLE "vasculopathy" is reported. Recently, an association of NLE and hydrocephalus has been recognized.¹²⁵ Chondrodysplasia punctata, a stippling of the epiphyses, and pulmonary capillaritis are rare clinical presentations of NLE.^{123,126}

In a prospective multicenter study of 128 infants whose mothers had been referred for the presence of anti-SSA/Ro antibodies, regardless of their diagnosis, hematologic abnormalities and raised liver enzymes were seen in 27% and 26%, respectively.¹²⁷ Cutaneous NLE manifestations were present in 16%. Only 2 of the 128 infants (1.6%) presented with complete CHB. In a recent Japanese review, 193 infants with NLE were described reporting CHB in 23%.¹²⁸

Treatment of CHB in NLE remains controversial. Prevention of progression to complete CHB may be achieved by treating the mother with fluorinated steroids (dexamethasone or betamethasone), which are not metabolized by the placenta and are available to the fetus in an active form. IV immunoglobulin had been used to prevent the development of CHB in the index patient and in subsequent pregnancies.¹²⁹ The current recommendation is to screen anti-Ro/SSA antibody-positive mothers with serial echocardiograms and obstetric sonograms biweekly starting from week 16 of gestation. Early detection of cardiac manifestations of NLE including premature atrial contractions or moderate pericardial effusion preceding CHB may potentially be targeted with preventive therapy.¹²⁹⁻¹³¹ First-degree heart blocks can be reversed by dexamethasone treatment of the mother.¹³² Once third-degree block is unequivocally identified, reversal is unlikely to be achieved. The majority of children with CHB require pacemakers.¹²¹

The treatment approach to extracardiac manifestations of NLE is conservative. Skin disease may require topical corticosteroids and sun protection.¹³³ Transient elevations of LFTs and cytopenias commonly do not require therapy.¹²⁴

The morbidity of cardiac neonatal lupus is estimated to be 20%.¹²¹ Mortality is particularly high in patients with CHB and concurrent cardiomyopathy. Children with NLE can develop SLE later in life. Concerns of potential long-term neurocognitive deficits of NLE patients need further evaluation.¹³⁴

JUVENILE DERMATOMYOSITIS

Definition and Criteria

Juvenile dermatomyositis (JDM) is an inflammatory, immune-mediated vasculopathy with predominant involvement of muscle and skin that may involve other organs as well. JDM is by far the most common form of idiopathic inflammatory myopathy (IIM) in children and adolescents; therefore other types (such as juvenile polymyositis) are not addressed in this chapter.

Epidemiology

The incidence of JDM has been reported at approximately two to three cases per million children¹³⁵⁻¹³⁷ with a mean age of onset of JDM of 6 to 9 years of age.^{136,138-141} JDM may begin before 4 years of age in approximately 25% of cases.¹³⁹ Females are affected more commonly than males in a ratio of approximately 2:1.^{136,138-141} Birth distributions for some subgroups of JDM patients have been noted and suggest that perinatal exposures may influence the onset of disease.¹⁴²

Genetics, Etiology, and Pathogenesis

It is thought that JDM is an autoimmune disorder in which environmental factors trigger an immune vasculopathy in genetically susceptible individuals. There is circumstantial evidence supporting the possible role of infection in the pathogenesis of JDM.^{139,143} Gene expression profiling in newly diagnosed JDM patients demonstrated interferon signature patterns in affected muscle tissue, suggesting preceding viral infection.¹⁴⁴ Electron microscopic studies of affected muscle demonstrate tubuloreticular inclusions, which can also indicate a type I interferon response. Many different infections have been associated with JDM.

Both human leukocyte antigen (HLA) and non-HLA genetic relationships have been reported to be disease associated or protective. In Caucasians, the HLA allele HLA DRB1*0301 is the strongest HLA risk factor (odds ratio [OR], 3.9). The HLA associations do not seem to affect disease course or complications.¹⁴⁵ Similarly, the presence of polymorphisms of cytokine genes may confer an increased risk on the development of JDM or may be protective.¹⁴⁶ Polymorphisms at these and other alleles may also be associated with disease complications and course.

The central events of the immune angiopathy of JDM include an overexpression of major histocompatibility complex (MHC) type I molecules on the surface of myofibers and a type I interferon response.¹⁴⁷ An immune complex-mediated vasculopathy with the presence of the C5-9 membrane attack complex, as well as immunoglobulins and C3 complement with complement activation, is evident. There is also a perivascular and perimysial infiltration of plasmacytoid dendritic cells, leading eventually to infiltration by CD4⁺ T cells, B cells, macrophages, proinflammatory cytokines, and chemokines. This leads to vascular damage, capillary dropout, and muscle ischemia. Upregulation of MHC class I molecules on myofibers is associated with the activation of nuclear factor κ B (NF κ B), which can lead to muscle damage. Maternal microchimerism has been noted in the majority of patients with JDM and in frequencies much greater than siblings or healthy controls,¹⁴⁷ suggesting that mechanisms similar to graft-versus-host disease may also play a role in the pathogenesis of JDM.

Clinical Features

Patients usually present with an insidious onset of fatigue, decreased functional ability, stiffness, and weakness. Irritability may result from muscle pain and an inability to

Table 108-2 Clinical Features at Presentation of Juvenile Dermatomyositis^{136,140,148-151,418}

Clinical Feature	% Patients Affected
Proximal muscle weakness	82-100
Characteristic rash (Gottron papule \pm heliotrope)	66-95
Calcinosis	5-30
Dysphagia	18-44
Dyspnea	5-43
Arthritis	23-61

participate in routine activities, especially in young children. A more acute onset, with fever, may occur in about half of patients. Weakness with rash is the presenting problem in about 50% of cases, weakness alone in about 25%, and the remainder present with predominantly skin symptoms. The clinical features at presentation are shown in Table 108-2.^{136,140,148-151}

Symmetric proximal muscle weakness typically presents first in the lower extremities, manifesting as difficulty climbing stairs and running. Patients may demonstrate a Gower sign reflecting weakness of the lower limb and trunk muscles. Reaching for objects above the head and hair brushing are difficult because of weakness of the shoulder girdle. An increased lumbar lordosis results from weakness of the trunk muscles, which also makes it difficult to roll in bed and get out of bed. Neck flexor weakness makes it difficult to hold the head upright. The muscles may be painful and tender to touch due to edema. Weakness of the distal musculature is unusual but may be present late in disease. Weakness of the palatal musculature results in dysphonia, dysphagia, and nasal regurgitation.¹⁵² Rarely, patients may be so weak as to be bedbound.

Skin rashes are present in approximately 75% of patients at presentation. Rash may be the presenting feature and in fact the only symptom (clinically amyopathic dermatomyositis), although subtle abnormalities may be detected on muscle MRI. Some skin features are predictive of poor outcome such as calcinosis and severe nail-fold capillary abnormalities.

The cutaneous features of JDM have been well summarized in a comprehensive review.¹⁵³ It is important to note that activity of the skin disease frequently does not correlate with activity of the muscle disease, and cutaneous abnormalities may have a significant impact on the patient's quality of life.

Gottron papules occur over the extensor surfaces of the metacarpophalangeal (MCP) and interphalangeal (IP) joints, as well as the knees, elbows, and medial malleoli (Figure 108-3A). They are erythematous to violaceous papules and may have associated scaling, crusting, erosions, ulcerations, or pigmentary change. This is differentiated from Gottron sign, which involves macular lesions occurring in the same distribution.

The pathognomonic heliotrope rash consists of violaceous to erythematous discrete or confluent macules confined to the upper eyelids (Figure 108-3B). This can extend periorbitally and often presents with generalized periorbital edema with discoloration.

Other cutaneous lesions include erythematous lesions in both sun-exposed and non-sun-exposed areas. Common

Figure 108-3 Fifteen-year-old boy with newly diagnosed juvenile dermatomyositis demonstrating Gottron papules over the metacarpophalangeal and proximal interphalangeal joints (A), heliotrope rash with periorbital swelling (B), and nail-fold capillary dropout, dilatation, and tortuosity (C). D shows a 4-year-old boy with juvenile dermatomyositis with a cutaneous ulcer adjacent to his right axilla. He died 3 months after presentation.

areas of involvement include the cheeks, the shawl area of the shoulders, and the “V” area of the lower anterior neck and chest wall. As opposed to SLE, the malar rash of JDM often involves the nasolabial folds and may involve the chin and forehead as well. Both the shawl sign and “V” rash are associated with anti-synthetase antibodies. Linear erythematous lesions may occur over extensor surfaces including the tendons of the hands and feet.

Vasculopathy is the characteristic pathologic feature of JDM. Cutaneous manifestations of vasculopathy include livedo reticularis and ulceration (Figure 108-3D). Ulcerative lesions are more common over extensor surfaces and the inner canthi of the eye. Erythema and capillary dilatation of the gingiva are a part of the vasculopathic manifestations. Capillary nail-fold changes are a major manifestation of JDM and are often visible to the naked eye. These are best observed under a microscope, but excellent resolution may be obtained by placing a drop of oil or water at the nail bed and magnifying this with a dermatoscope, otoscope, or ophthalmoscope at plus 40 diopters (Figure 108-3C). Characteristic changes include dilatation of the vessels, tortuosity, bushy capillaries, dropout, hemorrhage, and thrombosis. The severity of the capillary change may reflect the degree of disease activity and may also correlate with damage.

Calcinosis cutis can occur in up to 40% of patients with JDM; occasionally it may be present at the time of diagnosis.

It is a dystrophic calcification and occurs more often in patients who have been “undertreated” or had a delay in the start of treatment. Calcinosis may take several forms: superficial plaques and nodules; tumoral; fascial plane deposition; and an exoskeleton (Figure 108-4A,D). Patients may have more than one pattern. The superficial lesions are often subject to minor trauma and can lead to skin breakdown. They may also extrude a chalklike material (see Figure 108-4A). Tumoral deposits can impair function and lead to skin breakdown, especially when they involve flexural areas. Occasionally the calcinosis in these areas leads to an intense inflammatory reaction resembling cellulitis. Fascial plane calcinosis may impair function when crossing joint lines (see Figure 108-4B). An exoskeleton may give a scleroderma-like picture. Contrary to old beliefs that calcinosis was purely a healing process indicating that JDM was inactive, these lesions are often associated with ongoing active disease requiring more aggressive systemic treatment.

Lipodystrophy is a late manifestation reported in up to 40% of patients, developing a median of 4.6 years after diagnosis.¹⁵⁴ It may be localized, partial, or generalized and frequently occurs with metabolic syndrome, which includes hyperglycemia, hypertriglyceridemia, insulin resistance, hepatomegaly, transaminitis, and premature organ failure. Acanthosis nigricans may occur as well.

Figure 108-4 **A**, Elbow and forearm of a 14-year-old girl with chronic continuous juvenile dermatomyositis showing multiple sites of tumor calcinosis. Several of these, particularly over pressure points, have ulcerated extruding a chalklike material. **B**, Solitary site of tumor calcinosis posterior to the knee resulted in limited range of motion. **C**, Fascial and tumor calcinosis affecting the lower extremity. **D**, Same patient as in **A** demonstrating marked calcification giving an exoskeleton-like appearance across the chest wall.

Clinically amyopathic JDM (CAJDM) is a unique form of JDM in which patients have a characteristic skin rash in the absence of any abnormalities of muscle including MRI changes for at least 6 months.¹⁵⁵ Some patients have cutaneous changes and no weakness but abnormal muscle tests and may be categorized as “hypopathic JDM.”¹⁵⁶ In a systematic review, 26% of 68 patients with CAJDM developed classic JDM, with weakness developing a mean interval of 1.9 years after the onset of cutaneous symptoms; calcinosis developed in 4%. No laboratory or ancillary muscle testing was predictive of the development of muscle disease. Therefore immunosuppressive treatment is generally not indicated (other than required for the skin disease), but close follow-up is essential.

GI manifestations include dysphagia from both palatal muscle weakness and involvement of the distal esophagus. Intestinal vasculopathy can result in diffuse abdominal pain, lower GI bleeding, or bowel perforation with peritoneal free air.

Arthritis occurred in 61% of patients in one cohort, reported a median of 4.5 months after the JDM onset.¹⁵⁷ Osteopenia may result from disuse and treatment, and pathologic fractures may develop. Rhabdomyolysis is a rare complication that may follow infection.

Multiple respiratory manifestations may occur and are often subclinical. In one large case series followed for a mean of 16.8 years,¹⁵⁸ a low total lung capacity (TLC) was found in about 25% and a low diffusing capacity for carbon

monoxide (DLco) in about 50% of patients. Just over one-third of patients had abnormalities on high-resolution computed tomography (CT) scanning such as interstitial lung disease, chest wall calcinosis, and airway disease. Spontaneous pneumothorax has been reported.

Cardiac manifestations are uncommon and can include pericarditis, myocarditis, and arrhythmias. However, subclinical left ventricular diastolic dysfunction, systolic hypertension, and electrocardiogram abnormalities occurred in 22% of one series of patients and were associated with cumulative organ damage.¹⁵⁹ Hypertension is usually associated with high-dose glucocorticoid therapy.

The association with malignancy is limited to case reports such that a search for malignancy is not required in children with JDM.

Disease Monitoring

Muscle enzyme levels are frequently normal soon after treatment and are therefore unreliable indicators of disease activity. Several tools have been developed and validated to monitor the course and outcome of children with JDM. These include the 0- to 10-point Manual Muscle Test,¹⁶⁰ the Childhood Health Assessment Questionnaire (CHAQ),¹⁶¹ the Childhood Myositis Assessment Scale (CMAS),¹⁶² the Disease Activity Score (DAS),¹⁶³ the Myositis Damage Index (MDI), and the Intention to Treat Index (MITAX). The Myositis Disease Activity Assessment Visual Analogue Scale (MYOACT) consists of a series of 10 visual analogue scales in different organ systems.¹⁶⁴ In 2008 a prospective validation study of a core set for the evaluation of response to therapy in JDM was published under the auspices of the Paediatric Rheumatology International Trials Organization, the ACR, and the European League Against Rheumatism (EULAR) (Table 108-3).¹⁶⁵ Provisional criteria for the evaluation of response to therapy in JDM include at least 20% improvement from baseline in three of six core set variables with no more than one of the remaining

worsening by more than 30%, which cannot be muscle strength.¹⁶⁶ The Cutaneous Assessment Tool has undergone preliminary validation in a series of 113 children with JDM. It measures both skin activity and skin damage.^{167,168}

Diagnosis and Diagnostic Tests

The diagnostic criteria published by Bohan and Peter^{169,170} require that patients have a characteristic skin rash plus three of the following four to meet the definition of “definite” JDM: symmetric proximal muscle weakness, elevated serum levels of muscle-derived enzymes, myopathic electromyogram (EMG), and histologic evidence of myositis. Patients with rash and two of these four criteria may be diagnosed with “probable” JDM. Because both EMG and biopsy are invasive procedures, many practitioners now rely on MRI studies of muscle to support the diagnosis (see later).

Laboratory evaluation in children with JDM helps to support the diagnosis and exclude other causes of muscle weakness. Systemic markers of inflammation such as the ESR and CRP generally reflect the degree of disease activity. Serum levels of neopterin and elevated levels of CD19⁺ B lymphocytes have been suggested as good markers of disease activity, as has von Willebrand factor.¹⁷¹

Elevated serum levels of muscle enzymes form one of the diagnostic criteria of JDM. Measurements of creatine kinase, lactate dehydrogenase, aspartate transaminase, and aldolase should all be obtained. However, their degree of elevation does not necessarily correlate with active disease and they can occasionally be normal, even at presentation, particularly with long-standing disease. Serum levels of muscle enzymes drop dramatically with treatment, often before a clinical improvement is seen.

Electromyography has generally fallen out of favor despite still being part of the diagnostic criteria, especially if MRI is available. Characteristic EMG changes include spontaneous fibrillations, increased insertional activity, decreased amplitude, and duration of action potentials.

Although abnormal muscle biopsy is one of the criteria proposed by Bohan and Peter in the diagnostic criteria for juvenile dermatomyositis, many clinicians elect not to do muscle biopsies when patients present with classic clinical features of JDM. This is because the procedure is invasive, painful, may not add to the diagnostic accuracy in individual patients, and may be normal in up to 20% of patients. Normal results may occur because of sampling error or patchy muscle involvement. Better yield might be afforded through the use of MRI to determine best sites for biopsy. Care should be taken not to biopsy a site that has previously undergone electromyography.

The characteristic light microscopic features are suggestive of an inflammatory vasculopathy. This includes endothelial cell swelling, capillary dropout with a reduced capillary-to-muscle fiber ratio, microthrombosis, and infarction. There is a relatively sparse inflammatory infiltrate consisting mainly of T cells, but there may be myeloid cells present as well. Muscle fibers demonstrate perifascicular atrophy, overexpression of class I major histocompatibility complex, deposition of immunoglobulin, and the membrane attack complex C5-9. There are also areas of degenerating and regenerating muscle fibers. Chronic

Table 108-3 Domains and Suggested Variables Included in the Final Core Set for the Evaluation of Response to Therapy in Juvenile Dermatomyositis (JDM)

Domain	Suggested Variables
Physician's global assessment of patient's overall disease activity	10-cm VAS
Muscle strength	CMAS (or MMT)
Global JDM disease activity tool	DAS (or MYOACT or MITAX)
Parent's global assessment of patient's overall well-being	10-cm VAS
Functional ability assessment	CHAQ
Health-related quality of life assessment	CHQ physical summary score

CHAQ, Childhood Health Assessment Questionnaire; CHQ, Child Health Questionnaire; CMAS, Childhood Myositis Assessment Scale; MITAX, Myositis Intention to Treat Index; MMT, Manual Muscle Test; MYOACT, Myositis Disease Activity Assessment; VAS, Visual Analogue Scale.

From Ruperto N, Mistorio A, Rivelli A, et al: The Paediatric Rheumatology International Trials Organisation provisional criteria for the evaluation of response to therapy in juvenile dermatomyositis, *Arthritis Care Res (Hoboken)* 62:1533–1541, 2010.

changes include an increase in the perimysial and endomysial connective tissue, thought to reflect muscle fiber damage and loss. Histopathologic changes have been shown to correlate with both ulcerative disease and poor prognosis.¹⁷²

Recently, an international group has developed a scoring system that can be used in routine laboratories. The scoring tool uses four domains to reflect the degree of pathology: inflammatory, vascular, muscle fiber, and connective tissue. It also includes a visual analogue scale from 0 to 10 to reflect overall damage.¹⁷³

Currently the diagnosis of JDM is made on the basis of Bohan and Peter criteria. However, many pediatric rheumatologists now have turned to MRI to assist with the diagnosis and avoid more invasive tests such as EMG and muscle biopsy.¹⁷⁴ Inflammation characteristic of JDM is seen as high-signal intensity on fat-suppressed weighted and short tau inversion recovery (STIR) images.¹⁷⁵ STIR sequences can also reveal fasciitis and panniculitis. Muscle atrophy is best appreciated on T1-weighted sequences as increased signal between muscle planes. An increase in mean T2 relaxation time correlates with increased muscle disease activity and muscle strength.¹⁷⁶

ANA positivity is seen in 10% to 85% of patients with JDM. Myositis-associated (MAA) and myositis-specific antibodies (MSA) are uncommon unless the JDM is part of an overlap syndrome.^{177,178} In those patients who are positive for MAAs and MSAs (anti-signal-recognition particle, anti-synthetase, and anti-Mi2), the clinical associations are the same as in adult disease. The newly described autoantibody anti-p155/140 has been identified in up to 29% of one series of JDM patients,¹⁷⁹ and anti-p140 has been identified in 23% of JDM patients, associated with calcinosis in one series.¹⁸⁰

Differential Diagnosis

The most important differential diagnosis for patients presenting with rash and muscle weakness is SLE, particularly for those patients presenting with significant arthritis and a malar rash. Characteristic autoantibodies of SLE, cytopenias, renal disease, and hypocomplementemia help to differentiate these disorders. Patients with systemic sclerosis and prominent myositis may be difficult to differentiate from patients with JDM. Patients with mixed connective tissue disease and other overlap syndromes may have features of JDM in addition to those of other autoimmune connective tissue diseases.

Other idiopathic inflammatory myopathies are extremely rare in children. These include inclusion body myositis, granulomatous myositis, and macrophagic myositis.

Patients who present with either no rash or mild rash and predominant muscle weakness may need to be differentiated from patients with primary myopathies. Patients with muscular dystrophies often have positive family histories and an insidious onset of disease with characteristic muscle groups involved. Congenital myopathies usually present in infancy with hypotonia. Metabolic myopathies may be associated with developmental delay. Cramping and weakness after exertion may also be signs of metabolic myopathy.

Various infections may lead to an acute myositis. Perhaps the best recognized is influenza B, presenting with acute calf

pain, weakness, and raised muscle enzyme levels. *Trichinella* infection may be associated with periorbital edema and significant peripheral eosinophilia. Many other bacteria, viruses, and parasites may cause myositis; they should be suspected in the appropriate clinical circumstance.

Treatment

The management of patients with JDM requires a multidisciplinary team approach with medical specialists (rheumatologists, dermatologists, neurologists); nurses; rehabilitation specialists; social workers; and nutrition specialists.

Early aggressive treatment has been shown to result in better long-term outcomes and prevent disease-related complications.^{139,141,181,182} The cornerstone of treatment is high-dose, daily corticosteroid, usually combined with a second-line agent, typically methotrexate (MTX). Some practitioners advise the early use of high-dose, IV pulse methylprednisolone to ensure appropriate absorption when there may be a concern of intestinal vasculitis,¹⁸³ when there is a flare of disease, or when a patient seems unresponsive to standard steroid therapy. The usual course has been to start at 2 mg/kg/day in one to three divided doses and to begin to taper when muscle enzymes have normalized and strength has improved, with a subsequent slow taper over 18 to 24 months in uncomplicated cases. With steroid treatment alone, a significant number of patients do not respond fully and have complications, and some patients may be overtreated and have steroid-related complications. As a result, other agents are commonly prescribed.

MTX has been used for decades in children with steroid-resistant JDM and has recently been incorporated into many treatment protocols. In addition to its anti-inflammatory effect, it allows for a lower cumulative dose of corticosteroids.¹⁸⁴ A recent survey of North American pediatric rheumatologists documented that the most common treatment approach to patients with JDM is a combination of prednisone and MTX.¹⁸⁵

In patients who do not respond adequately, there are several options. IV immunoglobulin (IVIG) has been shown in a randomized controlled trial in adults with dermatomyositis to be effective,¹⁸⁶ as well as in case series in childhood JDM.¹⁸⁷ Several different protocols have been described. Generally, if there is no improvement within 2 months, it is unlikely that additional IVIG will be effective.

Mycophenolate mofetil at an initial dose of 20 mg/kg in two divided doses was studied in 50 patients who had not responded to prednisone and MTX.¹⁸⁸ A significant improvement in muscle and skin DAS was noted at 12 months, with a significant reduction on steroid dose and no serious adverse events. There was an increase in mean height and weight as well.

Cyclosporine A is used frequently in Europe as a second-line agent with good results.¹⁸⁹ A trial is currently under way in Europe for newly diagnosed patients with JDM comparing prednisone alone with prednisone plus MTX with prednisone plus cyclosporine A.

Cyclophosphamide has generally been reserved for patients with treatment-resistant disease, severe ulcerative disease, or lung involvement. Major clinical benefit was

noted in a small cohort of patients without serious toxicity.¹⁹⁰

The results with anti-tumor necrosis factor (TNF) treatment with both etanercept and infliximab have been reported in several small case series, with both positive and negative outcomes.¹⁹¹ There are reports of several cases of myositis developing while on etanercept treatment. The use of rituximab has been reported in only a small number of patients with good results.¹⁹² The results of the rituximab in myositis trial are awaited. Nevertheless, a trial may be warranted in patients with severe unresponsive disease. It is possible that patients who have myositis-specific autoantibodies would respond better. A few patients have undergone successful autologous stem cell transplantation.¹⁹³

One approach to the treatment of patients with JDM has been to use a step-wise addition of medications if patients fail to improve according to a predetermined outcome (similar to “treat-to-target” approach in rheumatoid arthritis). Using this approach, Kim and colleagues¹⁸² reported excellent outcomes in a series of patients who were treated, progressively, with prednisone (98%), MTX (78%), IV methylprednisolone (84%), cyclosporine A (27%), IVIG (20%), plasma exchange (8%), and cyclophosphamide (4%).

Recently, the Childhood Arthritis and Rheumatology Research Alliance (CARRA), using consensus building techniques, proposed three protocols for the treatment of moderately severe JDM. All include corticosteroids in one to two doses per day (maximum 60 mg) plus MTX, preferably given by the subcutaneous route at the lower dose. Clinicians may also add either pulse steroids or IVIG of 15 mg/m² or 1 mg/kg, maximum 40 mg/wk.¹⁹⁴ One approach to the pharmacologic management of JDM is listed in Table 108-4.

Cutaneous disease occasionally requires specific treatment irrespective of the treatment of the muscle disease. Sun protection with broad-spectrum sunscreens with an SPF of 30 or higher should be used daily. Topical emollients are helpful for dry and pruritic skin. Antihistamines may be helpful in reducing pruritus. Topical corticosteroids and tacrolimus may be indicated for the very inflamed lesions in patients who either do not respond to, or do not require, systemic therapy. Hydroxychloroquine was associated with a significant improvement of skin disease in a small cohort of patients who had an incomplete response to systemic corticosteroids.¹⁹⁵

Physiotherapy and occupational therapy are important to all children with JDM. Early in the disease, attention must be paid to stretching joints to prevent muscle contractures. Occasionally, contracted joints should be splinted. As the muscles heal, a more vigorous active exercise program can be initiated to strengthen muscles that may have atrophied from the combined effects of the inflammatory myopathy, disuse, and high-dose corticosteroid treatment. Active exercise may in fact exert anti-inflammatory effects in exercised skeletal muscle.¹⁹⁶

Treatment for calcinosis has been disappointing. Case reports with positive results have included bisphosphonates and calcium channel inhibitors, but most patients do not respond. Surgical excision may be necessary for particularly troublesome individual lesions and can have excellent results.

Table 108-4 An Approach to the Management of a Patient with Juvenile Dermatomyositis

For Muscle Weakness
Initial Treatment
Prednisone Methotrexate subcutaneously ± IV pulse methylprednisolone ± IVIG
If Failure to Respond to Initial Treatment, Consider Adding:
IV pulse methylprednisolone IVIg monthly Azathioprine Mycophenolate mofetil Cyclosporine A
If Failure to Respond to Second-Line Treatment, Consider Adding:
Cyclophosphamide Tacrolimus Infliximab Rituximab
For Skin
Initial Treatment
Hydration Sun protection
If Failure to Respond to Second-Line Treatment, Consider Adding:
Hydroxychloroquine Topical tacrolimus

IV, intravenous; IVIG, intravenous immunoglobulin.

Outcome

In the precorticosteroid era, approximately one-third of patients with JDM went into a complete clinical remission, one-third had a chronic course, and one-third died.¹⁹⁷ Advances in medical therapy, earlier diagnosis, and more aggressive treatment protocols have led to significantly improved outcomes; however, there is still significant morbidity and a small mortality associated. Current mortality is less than 5%.^{198,199}

Patients may follow one of three disease courses: monocyclic, polycyclic (flares of disease while off treatment), or chronic continuous courses. Delayed recognition of disease and initial undertreatment may result in more prolonged disease course. In the “modern era,” two large series showed that approximately 40% of patients pursued a monophasic course and the remainder had either a polycyclic or a chronic continuous course.^{141,199} Using an aggressive early stepwise treatment approach, only 4% had a chronic disease course, suggesting that early control of muscle inflammation prevents long-term morbidity.¹⁸²

The largest follow-up study included 490 patients from Europe and Latin America followed for a mean of 7.7 years seen between January 1980 and December 2004.¹⁹⁹ Reduced muscle strength and/or endurance were documented in 40% to 50%, although it was severe in less than 10% of patients. Persistent disease activity was noted in 40% to 60%. Cumulative damage occurred in 70%, primarily cutaneous. Decreased functional ability was reported in 40% and major impairment in 7%. A chronic course was the strongest predictor of poor prognosis.

There are a number of factors considered to predict a poor outcome including a delay in treatment or

undertreatment,¹⁸¹ chronic continuous course,¹⁹⁹ presence of rash and capillary nail-fold dropout at 6 months of treatment,¹⁴¹ ulcerative skin disease, and abnormalities on initial muscle biopsy.¹⁷² In addition, the presence of myositis-specific antibodies, unique HLA types, and the TNF polymorphism 308 may also determine a poorer outcome.

SCLERODERMA

The scleroderma disorders in children can be classified into systemic, localized, and others (Table 108-5). The systemic scleroses are rare in the pediatric age group and are outnumbered by the localized forms by approximately 10:1.

Systemic Sclerosis

Epidemiology

Juvenile systemic sclerosis (JSSc) makes up approximately 10% of all cases of systemic sclerosis²⁰⁰; the incidence rate in a recent U.K. study was reported as 0.27 per million children. Females outnumber males anywhere from 4:1²⁰¹ to 10:1.²⁰² The incidence seems to increase with increasing age,^{200,203} although in one large multicenter review the mean age of onset was 8.1 years.²⁰¹ Diffuse disease is much more common than limited disease. An increased family history of autoimmune disease including scleroderma has been noted in some series.

Little work on etiology and pathogenesis has been done specifically in juvenile systemic sclerosis, and it is assumed to be identical to adult disease. The interested reader is referred to Chapter 83.

Clinical Features

The onset of diffuse systemic sclerosis is often insidious, and delay in diagnosis ranged from a median of 1 to 2.8 years in three large series.²⁰⁰⁻²⁰² The most common presenting features are Raynaud's phenomenon, skin edema, and sclerodactyly (Table 108-6). The diagnosis should be considered suspect in the absence of Raynaud's phenomenon.

Although skin edema is the earliest cutaneous abnormality, it is followed fairly quickly by induration, sclerodactyly, and loss of facial creases.

CT, computed tomography; DLco, diffusing capacity for carbon monoxide; FVC, forced vital capacity.

Modified from Martini G, Foeldvari I, Russo R: Systemic sclerosis in childhood: clinical and immunologic features of 153 patients in an international database, *Arthritis Rheum* 54:3971–3978, 2006.

Raynaud's phenomenon involves the distal extremities and rarely other acral areas such as the earlobes and tip of the nose. Occasionally it may lead to digital infarcts resulting in pitting or more significant gangrenous change. Capillary nail-fold abnormalities, visible either to the naked eye or by capillary microscopy, have been reported in at least 50% of patients and include areas of dropout and abnormal capillaries with dilatation and tortuosity.

Abnormalities of the musculoskeletal system include mild inflammatory synovitis, which is nonerosive; joint contractures most commonly resulting from skin and subcutaneous tightness around the joints; and myositis. In patients with overlap syndromes the muscle involvement is

more significant. Otherwise scleroderma myositis is generally quite mild. Tendon friction rubs may be felt or heard in a minority of patients.

Involvement of the respiratory system has become the most significant cause of morbidity and mortality in patients with systemic sclerosis. Early changes may be documented by high-resolution computed tomography, although this may not offer much greater benefit than well-performed pulmonary function tests (PFTs).²⁰⁴ It is important to document the pulmonary status early in the disease process because it is only then, before irreversible fibrosis occurs, that reversal of abnormalities may be possible. Pulmonary function abnormalities include a reduced forced vital capacity, a reduced FEV₁-to-forced vital capacity (FVC), and a reduced DLco. Severe chest wall involvement with restriction of movement may also lead to abnormal PFTs. Early CT changes include a ground-glass appearance suggestive of alveolitis.²⁰⁵ Rarely, pleural effusions may occur. Cardiac involvement includes pericarditis (which may be asymptomatic), arrhythmia, and congestive heart failure (CHF). Pulmonary arterial hypertension may develop in the face of severe lung disease. Cardiac disease (resulting primarily from CHF) was the most common cause of mortality in one series of 135 patients with juvenile systemic sclerosis.²⁰⁶

Involvement of the GI system is common with symptoms of dysphagia and gastroesophageal reflux. More diffuse involvement can lead to reduced GI motility with bacterial overgrowth resulting in malabsorption. Severe constipation may occasionally occur. Renal involvement is much less common in juvenile than adult scleroderma and can include proteinuria, hypertension, and the eventual development of renal crisis. Neurologic involvement is unusual but can include seizure, stroke, and peripheral neuropathy.

Diagnosis and Diagnostic Tests

The diagnosis of systemic sclerosis rests on the presenting signs and symptoms and the investigation of organs that may be affected by the process. Seventy-five to 97% of patients were antinuclear antibody positive in three series.²⁰⁰⁻²⁰² Specific autoantibodies include anti-topoisomerase in approximately 33%, anticentromere antibody in less than 10%, and autoantibodies associated with overlap syndromes (anti-PM-Scl, anti-U1-RNP, anti-Ro) in a smaller number depending on the series. Rheumatoid factor may be present in up to 20% of patients.

Skin biopsy is rarely performed. Pathologic findings include dense collagenization and loss of adnexal structures. An inflammatory infiltrate composed primarily of mononuclear and mast cells is seen early in the course.

It is important to investigate the various organ systems that may be involved by systemic sclerosis in order to help prognosticate and develop an appropriate management plan. Investigations should include, at a minimum, PFTs with a DLco, an electrocardiogram, an echocardiogram, and a chest radiograph. For patients unable to perform PFTs, high-resolution CT scan is indicated. This is also indicated in patients with abnormal PFTs to detect early alveolitis. Serum KL-6 is a mucin-like glycoprotein strongly expressed in type II pneumocytes and may be a useful noninvasive marker of pulmonary fibrosis in children with JSSc.²⁰⁷

It can be assumed that most patients have GI involvement and that an upper GI series will be abnormal. This test is indicated for patients with severe pain unresponsive to standard agents and severe dysphagia. Hydrogen breath test and measuring fat-soluble vitamins may be helpful in patients with suspected malabsorption. Radiographs of the hands may be helpful in showing distal acro-osteolysis in patients with severe Raynaud's phenomenon and occasionally may show calcinosis.

When patients present with Raynaud's phenomenon, capillary nail-fold abnormalities, and edematous or indurated skin, the diagnosis is clear and the differential diagnosis is limited. However, patients are often seen early in the course with just Raynaud's phenomenon and a positive ANA. In those situations the most important differential diagnoses to consider are systemic lupus erythematosus, overlap syndrome/mixed connective tissue disease, and juvenile dermatomyositis. Although many other diseases are associated with skin fibrosis, they are not associated with the characteristic multisystem involvement as systemic sclerosis and should not pose a diagnostic challenge.

Provisional classification criteria have been developed and accepted by the Pediatric Rheumatology European Society (PReS), ACR, and EULAR on the basis of a Delphi survey and nominal group techniques.²⁰⁸ These were proposed because current criteria had not been studied in children and are not sensitive enough to detect early disease. Furthermore, they do not include key features of early disease such as Raynaud's phenomenon, ANA positivity, and capillary nail-fold changes. The proposed criteria are listed in Table 108-7. The presence of the one major and at least two minor criteria in a patient younger than 16 years classifies the patient as having juvenile systemic sclerosis, with a sensitivity of 90% and a specificity of 96%.

Treatment

The approach to the management of patients with systemic sclerosis should include treating the basic disease process itself, as well as the various organ manifestations. No controlled studies exist in children, and data must be extrapolated from the adult literature. The EULAR Scleroderma Trials and Research Group has made recommendations regarding management of patients with systemic sclerosis, and they should be considered for all patients.²⁰⁹ Because no specific treatment studies have been reported in children and adolescents, the reader is referred to Chapter 84 for a discussion of treatment where the same principles hold. It should be noted that for patients with rapidly progressive disease and progressive lung disease, autologous stem cell transplantation may provide the only opportunity for survival and has been successful in a number of patients with juvenile systemic sclerosis.²¹⁰

Outcome

Very little long-term outcome data are available for JSSc. Morbidity is substantial from the multisystem involvement with marked impact on the quality of life. The survival rates in juvenile systemic sclerosis are better than adult disease. Mortality in three large series varied from 12% to 30%.^{200,201,203} The most common causes of death include

Table 108-7 Provisional Criteria for the Classification of Juvenile Systemic Sclerosis (SSc)

Major Criterion (Required)
Proximal skin sclerosis/induration of the skin
Minor Criteria (At Least 2 Required)
Cutaneous
Sclerodactyly
Peripheral Vascular
Raynaud's phenomenon
Nail-fold capillary abnormalities
Digital tip ulcers
Gastrointestinal
Dysphagia
Gastroesophageal reflux
Cardiac
Arrhythmias
Heart failure
Renal
Renal crisis
New-onset arterial hypertension
Respiratory
Pulmonary fibrosis (HRCT/radiography)
Decreased DLco
Pulmonary arterial hypertension
Neurologic
Neuropathy
Carpal tunnel syndrome
Musculoskeletal
Tendon friction rubs
Arthritis
Myositis
Serologic
Antinuclear antibodies
SSc-selective autoantibodies (anticentromere, anti-topoisomerase I [Scl-70], antifibrillarin, anti-PM-Scl, antifibrillin or anti-RNA polymerase I or III)

DLco, diffusing capacity for carbon monoxide; HRCT, high-resolution computed tomography.

The presence of the 1 major and at least 2 minor criteria in a patient younger than 16 years classifies the patient as having juvenile systemic sclerosis, with a sensitivity of 90% and a specificity of 96%.

From Zulian F, Woo P, Athreya BH, et al: The Pediatric Rheumatology European Society/American College of Rheumatology/European League Against Rheumatism provisional classification criteria for juvenile systemic sclerosis, *Arthritis Rheum* 57:203–212, 2007.

cardiac (including pulmonary arterial hypertension) and respiratory failure. Factors considered to be significant predictors of mortality include fibrosis on chest radiograph, raised creatinine levels, and pericarditis, whereas a short disease duration at diagnosis may confer protection.²¹¹

Localized Scleroderma

Epidemiology

Localized scleroderma (LSc), also known as *morphea*, had a reported incidence of 2.7 per 100,000 of the general population in the Mayo Clinic series,²¹² and 3.4 per million children in the United Kingdom,²¹³ making it much more common than systemic sclerosis in the pediatric age group. The female-to-male ratio is approximately 2:1, and the average age of onset is approximately 7 years. Mild lesions may never get to medical attention, so the incidence may be even higher. Congenital morphea has been reported.²¹⁴ Several classification schemes have been developed; the proposed Pavia criteria are listed in Table 108-5.²¹⁵

Linear lesions are more common in the pediatric age group.^{213,216–218}

Etiology and Pathogenesis

Like systemic sclerosis, it is likely that environmental factors trigger immune activation leading ultimately to fibrosis. There have been no genetic studies to date to suggest that the HLA or non-HLA systems play a role, although those studies are under way. Familial occurrence is uncommon, but there is a strong family history of other autoimmune disorders.^{216,219} Trauma has been considered as a possible inciting feature.²²⁰ *Borrelia* infections have been implicated in Europe but not in North America. The presence of elevated levels of serum cytokines (such as TNF and interleukin [IL]-1) that may influence fibroblast proliferation provide strong evidence for the role of immune activation in disease pathogenesis.²²¹ Microchimerism has been reported, and as with other connective tissue diseases it suggests that mechanisms similar to graft-versus-host disease also may play a role. Several drugs and toxins may lead to cutaneous fibrosis, although none has been consistently identified in patients with LSc.

Clinical Features

There is usually a delay in presentation of several months because the lesions themselves are typically not symptomatic. Active circumscribed (Figure 108-5A) and linear lesions (Figure 108-5B) usually have a shiny, waxy appearance surrounded by a violaceous, erythematous border. They may be warmer than the surrounding and contralateral skin. Rarely there may be local itching or tingling. The lesions are indurated, and they may be either superficial or can extend to muscle and bone. Occasionally with linear lesions, extensive fascial involvement may occur. Lesions heal with hyperpigmentation or hypopigmentation and generally soften with time. Atrophy of the subcutaneous tissues is common. Linear lesions, if untreated, may result in growth deformity, joint contracture, loss of muscle bulk, and marked extremity weakness.

Lesions on the face and head can take the form of either a “saber-cut”-like lesion (*en coup de sabre*) or progressive hemifacial atrophy (also known as *Parry-Romberg syndrome*), where the epidermal changes are minimal but there is marked dermal and subcutaneous atrophy (Figure 108-5C). These may coexist in the same patient. With time, as the unaffected side of the face grows normally, there is progression of the facial asymmetry even though the disease may be inactive. Facial lesions may be associated with hemiatrophy of the tongue (Figure 108-5D), dental abnormalities, and ocular abnormalities. A small number of children develop seizures.²²²

Pansclerotic morphea is rare but can be life threatening. There is marked thickening of the skin and deeper tissues involving the extremities and trunk, sparing the distal extremities. Although it is similar to systemic sclerosis in the extent of the fibrosis, internal organ involvement does not occur and Raynaud's phenomenon is not common.

Extracutaneous signs and symptoms have been reported in up to 20% of patients.²¹⁶ They are more common in patients with linear lesions. The most common is arthritis,

Figure 108-5 **A**, Circumscribed/plaque morphea on the abdomen of a 5-year-old girl with localized scleroderma. Note the central ivory-colored area of induration surrounded by intense erythema indicative of an active lesion. **B**, Linear localized scleroderma involving the inner aspect of the left leg of an 11-year-old girl. Note areas of porcelain-white lesions surrounded by erythema. **C**, A 10-year-old girl with a history of linear scleroderma of the face with both en coup de sabre and Parry-Romberg lesions of 7 years' duration. Note frontal alopecia and two bands of linear scleroderma on the right side of the forehead and face. There is hyperpigmentation and marked subcutaneous atrophy. Note also the loss of eyebrow and eyelashes on the right, small right nares, and thin lips on the right. **D**, Same patient as in **C** showing atrophy of the tongue.

not necessarily associated in the area of skin involvement. It is seen more commonly in patients with a positive rheumatoid factor. Neurologic manifestations of seizure and headache occur almost exclusively in patients with facial lesions. Ocular abnormalities including asymptomatic anterior uveitis were reported in 3% of one large series.²²³

Diagnosis and Diagnostic Tests

The diagnosis of LSc is usually made on the basis of characteristic cutaneous features. A skin biopsy can be of assistance when the diagnosis is not clear. Abnormalities consist of edema, an early infiltration by mononuclear cells, and excessive deposition of collagen. With time there is loss of skin appendages and rete pegs. Other skin diseases that may have a similar clinical presentation include lichen sclerosis et atrophicus, connective tissue nevus, collagenoma, and localized fibrotic disorders. The absence of significant internal organ involvement and Raynaud's phenomenon help differentiate LSc from systemic sclerosis and other autoimmune conditions.

Laboratory investigations are nonspecific and show mild or no systemic inflammation (ESR, CRP). Eosinophilia and

hypergammaglobulinemia have been reported to correlate with active lesions,²²⁴ but this is not always the case. Rheumatoid factor is present in 10% to 25% and ANA positivity in approximately 50% of cases. Multiple specific autoantibodies have been reported, but antibodies to topoisomerase-I and centromere are distinctly unusual.^{221,225}

Treatment

The treatment of localized scleroderma depends on the stage of the lesion, as well as the extent of involvement. Few controlled studies have been done; therefore treatment recommendations have relied on general experience. Plaque lesions can generally be treated topically with either corticosteroids and/or calcipotriene.²²⁶ Markedly indurated lesions may respond better to imiquimod.²²⁷ Topical tacrolimus may also be used. Systemic treatment is usually indicated for rapidly progressive lesions, for lesions crossing joint lines, and for lesions that are potentially cosmetically deforming. A combination of corticosteroids and MTX is generally recommended.²²⁸⁻²³¹ Corticosteroids may be administered as monthly pulses or orally in a dose of 1 to 2 mg/kg with a taper over 3 to 6 months. MTX is

administered at a dose of up to 1 mg/kg or 15 mg/m² weekly. At higher doses, the subcutaneous route is probably more effective. Treatment should be administered for at least 2 years, and 1 year after all activity has disappeared because there is about a 30% chance of recurrence if treatment is stopped too early. MMF may be used for patients who have not responded to this combination.²³² Imatinib, cyclosporine A, and tacrolimus have also been effective in a small number of cases. Ultraviolet A therapy is used more frequently in Europe with good success.²³³ Autologous stem cell transplantation may be required for patients with pansclerotic morphea.

Patients with facial lesions have undergone cosmetic repair with generally good outcomes.²³⁴ Surgery may also be required to lengthen Achilles tendons.

In addition to medical and surgical treatment, a combined team approach is often required for patients with more extensive disease. Physical and occupational therapy are essential in improving and maintaining muscle strength, range of motion, and function. Psychosocial support is especially helpful for patients with facial lesions. Other medical personnel whose involvement may be required are neurologists, ophthalmologists, craniofacial surgeons, orthopedic surgeons, dentists, and orthodontists.

Disease Monitoring

To date, it has been difficult to monitor the course of the disease as clinicians have relied on insensitive measures such as warmth, color change, and change in size over time. Recently, some more objective measures have been studied including ultrasound,²³⁵ computerized skin score,²³⁶ and laser Doppler flow.²³⁷ A disease activity score has recently been developed,²³⁸ and initial validation of a disease damage score has been undertaken.²³⁹ CARRA is currently establishing scores for activity and damage.

Outcome

Lesions tend to soften spontaneously over several years and to heal with pigmentary change (usually hyperpigmentation) and subcutaneous atrophy. Linear limb lesions may lead to marked atrophy and joint contracture. Lesions may recur after many years of apparent inactivity. Neither self-esteem nor health-related quality of life appear to be diminished compared with controls, although not many patients with more disfiguring lesions were studied.²⁴⁰⁻²⁴² Rarely patients have developed other autoimmune connective tissue disorders including systemic sclerosis and SLE. Patients with pediatric onset of LSc have a higher incidence of autoimmune disorders as adults.²⁴³

Eosinophilic Fasciitis

Eosinophilic fasciitis (EF) is included by some within the classification of localized scleroderma,²¹² and several authors have reported that children with EF have a disease evolution to morphea.^{244,245} EF is extremely rare in the pediatric population. Affected children present with marked induration of cutaneous and subcutaneous tissues of the upper or lower extremities and occasionally the trunk or face. Its onset may be preceded by intense exercise. Raynaud's

phenomenon, internal organ involvement, and nail-fold capillary abnormalities are rare but may occur.²⁴⁶

Mixed Connective Tissue Disease

Mixed connective tissue disease (MCTD) was initially reported as a disorder associated with a favorable prognosis and an excellent initial response to low-dose glucocorticoid therapy. It had a frequency of 0.3% in the U.S. Pediatric Rheumatology Database. Children present with arthritis, myositis, and cutaneous disease characteristic of scleroderma, SLE, or JDM.²⁴⁷ A decrease in aerobic capacity may occur from reduced muscle strength.²⁴⁸ Progression to a more scleroderma-like disease has occurred, with sclerodactyly and GI involvement, or an SLE-like disease may evolve.²⁴⁹⁻²⁵¹ Nephritis may be more frequent and more severe in children than in adults. Children often have less pulmonary disease (hypertension) and more hematologic complications (thrombocytopenia) than adults. ANAs are present in high titers, often in a speckled pattern, to an extractable nuclear antigen and ribonuclear protein (RNP).

VASCULITIS

Vasculitis is a common clinical phenomenon in children. Vasculitis can occur in association with infections, medications, hypersensitivity reactions, and in the context of childhood systemic rheumatic diseases such as lupus. The most common primary or idiopathic vasculitis types are Henoch-Schönlein purpura (HSP)²⁵² and Kawasaki disease (KD).²⁵³ Incidences of vasculitis subtype vary widely depending on characteristics of populations such as ethnicity and the method of ascertainment.

Similar to adults, childhood vasculitis is categorized by predominantly affected vessel size as small, medium, or large vessel vasculitis.²⁵⁴ The histopathologic characteristics vary between diseases and include karyorrhexis, neutrophilic infiltration and necrosis, giant cell formation, and lymphocyte infiltrates. In 2005 a classification system for childhood vasculitis was proposed.²⁵⁵ In 2008 the so-called "EULAR/PRs endorsed consensus criteria for childhood vasculitis" were validated.^{256,257}

Small Vessel Vasculitis

Inflammation of the small vessels is the most common vasculitis subtype in children. Typically exposure to infectious agents, medications, hypersensitivity such as serum sickness, or systemic illness can cause migration of neutrophils through the vessel wall, leukocytoclasia, and fibrinoid necrosis. The resulting histologic diagnosis of leukocytoclastic vasculitis is a common result found on superficial punch biopsies done for suspected vasculitis. Additional immunofluorescence studies may reveal immunoglobulin (Ig) deposits along the vessel wall, evidence of immune complexes and/or complement activation. Deposition of IgA is the hallmark of HSP.

Henoch-Schönlein Purpura

HSP (or anaphylactoid purpura) is an IgA-mediated small vessel vasculitis predominantly affecting the skin and

causing a palpable purpura. Histologically, a leukocytoclastic vasculitis with extravasation of leukocytes and red cells, vessel wall damage, fibrinoid necrosis, and IgA1 deposition at the vessel wall and in the mesangium of the kidney can be found.²⁵⁸ Preceding upper respiratory tract infections are reported in more than 50% of children. A variety of bacterial and viral triggers, environmental stimuli, and host susceptibility factors such as autoinflammatory disease genes have been reported.²⁵⁹⁻²⁶² HSP can occur before or during the course of systemic diseases such as antineutrophil cytoplasm antibody (ANCA) vasculitis or Crohn's disease.²⁶³

IgA appears to play a pivotal role in the pathogenesis of HSP. Abnormal glycosylation of the hinge region O-linked glycan of IgA1 has been implicated in the etiopathology of HSP: Abnormal IgA1 molecules were found to have a higher tendency to aggregate, interact with IgG, and form IgA-IgG complexes and deposits in the kidney.^{258,264} Similarly, serum levels of galactose-deficient IgA1 are elevated in Caucasian and Asian patients with IgA nephropathy.²⁶⁵ Schmitt demonstrated deposits of IgA-binding streptococcal M protein in the skin and kidney of HSP patients directly linking infection and vasculitis.²⁶⁶ Wu studied the

role of leukotrienes and suggested that abnormally high levels of leukotriene B₄ and lipoxin A₄, potent activators of neutrophils, found in HSP patients with nephritis differentiate them from those without nephritis.²⁶⁷

Definition and Classification. HSP is the most common defined childhood small vessel vasculitis characterized by the classic triad of palpable purpura, arthritis, and abdominal pain. In 2006 EULAR/PReS-endorsed consensus criteria for HSP were proposed (Table 108-8). The sensitivity of these criteria was found to be 100%, the specificity 87%.²⁵⁷

Epidemiology. Overall the incidence of HSP is estimated at 10 to 20 per 100,000 children younger than 17 years old.²⁶⁸⁻²⁷¹ Boys are more commonly affected than girls; the male-to-female ratio was recently reported at 1.8:1.²⁷² Gardner-Medwin reported an annual incidence of 70.3 per 100,000 between the ages of 4 and 6 years in a population-based study.²⁶⁹ In contrast, HSP is a rare disease in adults but may have a severe course and poor renal outcome.²⁷³

Clinical Presentation. Purpura is the leading symptom of HSP. In a recent Italian study purpura was present in all

Table 108-8 European League Against Rheumatism/Pediatric Rheumatology European Society Endorsed Consensus Criteria for the Classification of Childhood Vasculitides²⁵⁷

Vasculitis Type	Classification Criteria
Predominant Small Vessel Vasculitis	
Henoch-Schönlein purpura	Palpable purpura (mandatory criterion) plus at least one of: Diffuse abdominal pain Any biopsy showing predominant IgA deposition Arthritis or arthralgia (acute, any joint) Renal involvement (any hematuria and/or proteinuria)
Childhood granulomatosis with polyangiitis ²⁹⁶	At least 3 of the following 6 criteria must be present: Abnormal urinalysis (hematuria and/or significant proteinuria) Granulomatous inflammation on biopsy (if a kidney biopsy is done it characteristically shows pauci-immune necrotizing glomerulonephritis) Nasal sinus inflammation Subglottic, tracheal, or endobronchial stenosis Abnormal chest radiograph or computed tomography Proteinase 3 ANCA or c-ANCA staining (sensitivity/specificity calculated for any positive ANCA)
Childhood microscopic polyangiitis	No proposed criteria; for description see text
Childhood Churg-Strauss syndrome	No proposed criteria; for description see text
Predominant Medium Vessel Vasculitis	
Childhood (systemic) polyarteritis nodosa	Biopsy evidence of necrotizing vasculitis or angiographic abnormalities (mandatory criterion) plus at least one of: Skin involvement (livedo reticularis, tender subcutaneous nodules, other vasculitic lesions, superficial or deep infarctions) Myalgia or muscle tenderness Systolic/diastolic hypertension (>95th percentile) Mononeuropathy or polyneuropathy Renal involvement (proteinuria, hematuria, impaired renal function)
Childhood cutaneous polyarteritis nodosa	No proposed criteria; for description see text
Predominant Large Vessel Vasculitis	
Childhood Takayasu's arteritis	Angiography of the aorta or its main branches and pulmonary arteries showing aneurysms/dilatation, occlusion or thickened arterial wall not due to fibromuscular dysplasia (mandatory criterion) plus at least 1 of: Pulse deficit or claudication Blood pressure discrepancy (>10 mm Hg) Bruit Hypertension Acute-phase reactant (erythrocyte sedimentation rate >20 mm/hr, C-reactive protein abnormal)

ANCA, antineutrophil cytoplasm antibody; c-ANCA, cytoplasmic antineutrophil cytoplasm antibody.

cases, arthritis/arthralgias in 74%, abdominal symptoms in 51% including intussusception in 0.6%, renal disease in 54% including severe nephropathy in 7%, and acute renal failure in 2%.²⁷² Scrotal edema was reported in 13%. Correspondingly, Dolezalova and colleagues²⁷⁰ described purpura present in 100% of Czech HSP patients; arthritis/arthralgia in 52%; abdominal pain and/or GI bleeding in 40%; hematuria/proteinuria in 15%; and genital involvement in 2.8%. Eye findings including anterior uveitis can be seen in HSP patients.²⁷⁴

Skin disease in HSP has a characteristic appearance: Petechial or palpable purpuric lesions are located on dependent areas including lower legs and feet, buttocks, and arms. Lesions can have different sizes and stages ranging from fresh petechial rashes to confluent bruises. An associated edema is commonly found, hands and feet appear puffy, and scrotal edema may be present in boys. Children younger than 2 years have been reported to have more significant edema. Lesions occur in waves, and skin disease in HSP is reported to last from 4 to 8 weeks.²⁷²

HSP arthritis is often painful, nonerosive, and nonmigratory. Ankles, knees, hands, and wrists are most commonly inflamed. Arthralgias are found in a similar distribution. GI symptoms are common in HSP patients including intermittent abdominal discomfort, pain, and vomiting. Abdominal complications including intussusception are rare; however, they always have to be considered when a child presents with HSP features and complains of abdominal pain and possibly associated bloody stools. Oftentimes bowel wall thickening on ultrasound is detected.

Overall renal disease in HSP occurs in 40% to 50% of children and manifests itself as microscopic hematuria or low-grade proteinuria, which completely resolves in the vast majority.²⁷⁵ Older children may be at higher risk for nephritis.²⁷⁶ Overall progression to end-stage renal disease occurs in 1% to 3% of children.²⁷⁷ Renal biopsies are done in children with renal compromise and histologically demonstrate IgA nephropathy.²⁷⁵ The degree of damage on renal biopsy and the degree of proteinuria predicts poor outcome.²⁷⁸ Reported 10-year renal survival rates for children undergoing renal biopsies for HSP ranged from 73% to 90%.^{279,280} Though uncommon in HSP, overall IgA nephropathy and HSP nephritis represent the most common chronic glomerulonephritis in childhood.²⁷⁷

Diagnosis and Diagnostic Tests. Children with HSP may have a raised erythrocyte sedimentation rate (ESR) (57%), elevated serum IgA (37%), and proteinuria (42%).²⁷² All children require serial urinalyses. Jauhola and colleagues²⁷⁶ demonstrated that HSP nephritis occurred on average 14 days after HSP diagnosis, and within 1 month in the majority of cases. The risk of developing HSP nephritis after 2 months was 2%. Laboratory tests or blood pressure measurement at onset did not predict the occurrence of nephritis. Overall specific diagnostic markers of HSP are not readily available. Alternative complement pathway markers including activated C3 and C4 were reported in children and adults and may be associated with disease progression.²⁷⁵ Urinary proteomic patterns and serum levels of galactose-deficient IgA1 are promising and are currently being studied.²⁸¹

Skin biopsies are done to confirm the diagnosis of HSP and to exclude differential diagnoses. Overlapping clinical

features may be found in infection, inflammation or medication associated leukocytoclastic vasculitis, rheumatic fever, poststreptococcal glomerulonephritis, lupus, and systemic vasculitis.^{282,283} Renal biopsies are performed in a select group of HSP patients.²⁷⁵

Treatment. In most children HSP is a benign disease and does not require specific therapy. There is significant variation demonstrated for inpatient therapy and evaluation of children with HSP, which may contribute to varying clinical outcomes.²⁸⁴ Immunosuppressive therapy of HSP targets severe disease presentations including nephritis and gastrointestinal vasculitis. In 2006, Ronkainen and co-workers published a randomized placebo-controlled trial demonstrating that prednisone reduces the severity of joint and abdominal pain, while having no effect on purpura, prevention of nephritis, or recurrence of HSP.²⁸⁵ A recent retrospective cohort study of 1895 children discharged with HSP between 2000 and 2007 from 36 tertiary care children's hospitals in the United States determined that early corticosteroid treatment was associated with significantly less abdominal surgery, endoscopy, and abdominal imaging during hospitalization suggesting a protective effect of corticosteroid therapy for abdominal complications of HSP.²⁸⁶ In contrast, a prospective study from Finland reported that corticosteroids although alleviating clinical symptoms, did not alter the clinical course of HSP during 6 months of follow-up. Prednisone prophylaxis did not affect the timing of the appearance of nephritis.²⁷⁶ The addition of cyclophosphamide did not show a benefit in adults with HSP nephritis in a small trial.²⁸⁷ A stepwise approach is often used, including the use of nonsteroidal anti-inflammatory medication for mild HSP, corticosteroids for moderate to severe HSP, and addition of angiotensin-converting enzyme (ACE) inhibitors for nephritis. Evidence is emerging that treatment with high-dose IV pulse methylprednisolone coupled with azathioprine or cyclophosphamide may be beneficial in patients with severe nephritis.²⁸⁸ Cyclosporine also has been successfully used for severe nephritis.²⁸⁹

Outcome. In the majority of children HSP is a self-limiting disease, which resolves within 4 to 6 weeks.²⁵⁸ Patients with microscopic hematuria and trivial proteinuria have an excellent prognosis.²⁹⁰ In contrast, 30% of pediatric HSP patient with nephritis will have renal impairment and 5% will develop end-stage renal disease.²⁹¹ Recurrence of HSP is seen in a third of patients; symptoms resolve within 4 to 6 weeks in the majority of patients. Children older than 8 years of age and those with nephritis are significantly more likely to experience recurrences.²⁹²

Antineutrophil Cytoplasm Antibody Vasculitis

The group of childhood systemic vasculitides associated with ANCA include granulomatosis with polyangiitis (GPA; formerly known as Wegener's granulomatosis), microscopic polyangiitis (mPA), and Churg-Strauss syndrome (CSS). The conceptual framework provided by the Chapel Hill Consensus Conference on the Nomenclature of Systemic Vasculitis is commonly accepted for childhood ANCA vasculitis. Necrotizing small vessel vasculitis of venules, capillaries, arterioles, and small arteries is the hallmark of ANCA vasculitis. Pathogenetic studies were not primarily done in children and are therefore not

covered here. Pauci-immune necrotizing and crescentic glomerulonephritis, as well as hemorrhagic pulmonary capillaritis, frequently present as pulmonary-renal syndrome. Limited phenotypes including pauci-immune glomerulonephritis with ANCA and nonrenal, upper respiratory tract, or limited GPA are commonly included in the group of ANCA vasculitides of children and adults.²⁹³ These diseases are rare in childhood. However, recent collaborative efforts such as “A Registry for Childhood Vasculitis (ARChiVe)” have substantially increased the knowledge and understanding of childhood ANCA vasculitis.^{257,294,295}

Definition and Classification

Granulomatosis with Polyangiitis. The proposed EULAR/PRIS-endorsed consensus criteria for GPA are shown in Table 108-8.²⁹⁶ The sensitivity as determined in the validation process described earlier was found to be 93.3%, and the specificity was 99.2%, when including evidence of any ANCA. Cabral and colleagues²⁹⁴ have recently validated the proposed criteria in a large multicenter cohort of children with systemic vasculitis (no HSP) and determined a diagnostic sensitivity of 73.6% and specificity of 73.2%.

Microscopic Polyangiitis. In children, MPA is a rare diagnosis.²⁹⁴ No formal classification criteria were proposed for MPA in children by the “EULAR conference expert group.” Instead, the existing Chapel Hill description was modified by formally adding ANCA.²⁹⁶

Churg-Strauss Syndrome. CSS (allergic granulomatosis) is even less common than MPA in children. No pediatric classification criteria exist, and therefore adult ACR criteria are commonly applied.²⁹⁷ The pediatric literature is limited to case reports and small series.^{298,299} A recent literature review identified a total of 33 children with a female predominance (male-to-female ratio, 0.74) with a mean age of 12 years.³⁰⁰ All patients had significant asthma and histologic evidence of eosinophilia and/or vasculitis. ANCAs were only found in 25%. Children with CSS typically present with a necrotizing vasculitis affecting the lungs, GI system, peripheral nerves, heart, skin, and kidneys along with a history of severe asthma, other allergic symptoms, and peripheral and tissue eosinophilia.³⁰¹

Epidemiology

Childhood ANCA vasculitis is a rare group of diseases.³⁰² In Southern Alberta, Canada, the average annual incidence of GPA in children was estimated at 2.75 cases per million per year, with a steep increase over the past 5 years to 6.39 cases per million per year.³⁰³ A recent study from Japan reported the adult MPA incidence at 14.8 per million, whereas GPA was present in 2 per million adult patients.³⁰⁴ Within the group of ANCA vasculitis, MPA may be more common than GPA in adults, while it is definitely less common in children.^{294,305} However, Reinhold-Keller and associates suggested that the incidence of GPA of all age groups was two to three times greater than those of MPA and CSS. There was no regional difference in incidence rates found.³⁰⁶ Girls are consistently more commonly affected than boys; the male-to-female ratio is reported to be 1:3 to 4.³⁰⁷

Clinical Presentation

The clinical presentation of ANCA vasculitis is widely overlapping.³⁰⁸ In children, GPA and MPA patients are commonly reported in combined series. In the largest single-center cohort of 25 children,³⁰⁹ the median duration of symptoms before establishing the diagnosis was 2 months. Children presented most frequently with constitutional symptoms (96%) and glomerulonephritis (88%) with renal failure in half. Recovery from renal failure was uncommon (1/11). Upper airway disease was present in 84% including one child with subglottic stenosis. Overall, 80% had pulmonary involvement at diagnosis, most commonly nodules (44%) and pulmonary hemorrhage (44%). Five children with pulmonary hemorrhage required ventilation, and four children had venous thrombotic events.³⁰⁹ The ARChiVe group reported 117 pediatric patients including GPA ($n = 76$), microscopic polyangiitis ($n = 17$), ANCA-positive pauci-immune glomerulonephritis ($n = 5$), CSS ($n = 2$), and unclassified vasculitis ($n = 17$). In the 65 of 76 who met ACR criteria for GPA, the median interval from symptom onset to diagnosis was 2.7 months (range, 0 to 49 months). The most frequently presenting features by organ system were constitutional (89%); pulmonary (80%); ear, nose, and throat (80%); and renal (75%).²⁹⁴ Zwerina and co-workers suggested that children compared with adults with CSS had a predominance of cardiopulmonary disease manifestations, less peripheral nerve involvement, and higher mortality.³⁰⁰

Diagnosis and Diagnostic Tests

Raised inflammatory markers including ESR and CRP, leukocytosis, and positive ANCAs are commonly found at diagnosis of ANCA vasculitis.^{294,309} Akikusa and colleagues³⁰⁹ documented ANCA positivity in 22 of 25 children. Cabral and co-workers identified cytoplasmic ANCA (c-ANCA) positivity in 66% of pediatric GPA patients, 93% of whom were anti-PR3 positive on enzyme-linked immunosorbent assay. Accordingly, 22% were perinuclear ANCA (p-ANCA) positive, of which 21% had anti-PR3 and 57% anti-MPO specificity.²⁹⁴

Endothelial cell markers including von Willebrand factor antigen, antiendothelial cell antibodies, and circulating endothelial cells are potential biomarkers.³¹⁰⁻³¹² Disease activity and damage tools are currently being developed based on modifications of the available adult vasculitis measures.

Treatment

The treatment of ANCA vasculitis in children is grounded in knowledge gained from studies in adults. No randomized trials or prospective observational studies are available in children. The recently reported EULAR recommendations for management of vasculitis synthesize the available evidence.^{313,314} Children commonly receive induction therapy with cyclophosphamide and high-dose corticosteroids for severe disease, followed by a combination maintenance regimen with either MTX or azathioprine plus low-dose corticosteroids.^{294,309} Children with limited disease may be

primarily treated with MTX and corticosteroids.²⁹⁴ In contrast, the initial treatment of CSS in children was corticosteroid monotherapy in 76% ($n = 33$), while only 24% received combination immunosuppressive therapy. In a retrospective series, Wright and Dillon³¹⁵ reported that therapeutic plasma exchange may be of benefit during the acute phase of childhood systemic vasculitis. New drugs including rituximab and other biologic therapies are increasingly used in children.³¹⁶ Supportive therapy regimens such as ACE inhibitors and antibiotic prophylaxis vary and have not been systematically studied in children with ANCA vasculitis.³¹⁷

Outcome

ANCA vasculitis is a relapsing/remitting chronic disease in children and adults. Phillip and Luqmani³¹⁸ calculated overall 5-year survival rates for GPA of all ages at 75%, MPA at 45% to 75%, and CSS at 68% to 100% at 5 years. The pediatric CSS literature review captured six deaths (18%), all related to the underlying disease, occurring after a mean disease duration of 14 months.³⁰⁰ Mortality rates may be falling as a result of more effective intervention, but they remain elevated substantially in severe disease. Early deaths were attributed to active disease (multiorgan failure, infection). Late deaths reflected the cumulative burden of disease and treatment in addition to comorbidities.³¹⁸

Disease activity has consistently been reported to be high at diagnosis of ANCA vasculitis in children.^{294,309} Risk factors associated with mortality or morbidity remain to be identified in children.

Medium-Sized Vessel Vasculitis

KD, polyarteritis nodosa (PAN), and cutaneous PAN are characterized by medium-sized muscular artery inflammation. KD is the most common cause of acquired heart disease in Western countries. Vessel wall histology on autopsies was recently reported to demonstrate a proliferative, granulomatous process with accumulation of monocytes/macrophages and rare occurrence of fibrinoid necrosis.³¹⁹ KD is a monophasic inflammatory disease that leads to transient coronary artery lesions in 20% to 25% of children, while coronary artery damage (e.g., aneurysms, stenoses) is found in 5 to 8% of treated patients.^{253,320} In contrast, PAN is a rare disease, with difficult-to-control chronic disease activity, and high morbidity and mortality rates.³²¹ Biopsy specimens demonstrate systemic transmural necrotizing vasculitis. Cutaneous PAN has a similar histology; however, in general it has a less severe disease course.³²²

Kawasaki Disease

Kawasaki disease (KD) is better classified as an inflammatory “syndrome.” Infectious triggers and possibly other environmental factors lead to a stereotypical inflammatory process in a susceptible host.^{323,324} Host susceptibility clearly differs between ethnic groups. This may be related to genetic polymorphisms of proinflammatory genes such as the signal transduction caspase-3 gene *CASP3* or the *ITPKC* gene, which encodes a regulator of T cell activation.^{325,326}

Genes involved in vascular remodeling such as matrix metalloproteinases may confer an increased risk of vessel damage and aneurysm formation.³²⁷

Definition and Classification. The diagnosis of KD remains grounded in recognition of a clinical pattern: Children, in whom the diagnosis of typical KD is made, present with a minimum of 5 days of fever plus at least four of five criteria including oral changes of cracked lips/strawberry tongue (as seen in 94%), bilateral nonpurulent conjunctivitis (92%), rash (90%), erythema and/or swelling of hands and/or feet (77%), and cervical lymphadenopathy (64%).³²⁸

The diagnosis of KD is more challenging in children with incomplete clinical features. In 2004 the American Heart Association (AHA) proposed an algorithm for diagnosing and treating suspected incomplete KD.³²⁹ Yellen and co-workers tested the performance in a retrospective multicenter series of 195 patients with KD and coronary artery aneurysms. The authors demonstrated that applying the AHA algorithm would have significantly increased the rate of IVIG treatment from 70% (classic KD criteria) to 97%³³⁰ and possibly prevented aneurysms. Similarly, Heuclin and colleagues recently demonstrated a significantly increased detection rate of KD—in particular incomplete KD with coronary lesion—when applying the AHA algorithm.³³¹

Epidemiology. KD primarily affects young children; 80% of cases occur in children younger than 5 years of age.³³² Boys are more commonly affected than girls; the male-to-female ratio is reported to be 1.4 to 1.9:1.³³³ Recurrence rates of KD are estimated at 3%.³³⁴ Atypical KD is more common in children younger than 1 year or older than 9 years of age, accounting for one-third of KD diagnoses in these age groups.³²⁸

Incidence rates clearly vary between ethnic groups. Asian children are at highest risk: In 2010, Park and colleagues recently reported an average annual incidence rate of KD in Korea of 113.1 per 100,000 in children younger than 5 years.³³⁴ In Japan, the annual incidence rate was even higher at 218.6 per 100,000 children younger than 5 years of age.³³² Around the same time, in the rest of the world annual KD incidence rates were reported between 5 and 13 per 100,000 children younger than 5 years.^{328,335-338}

Clinical Presentation. Fever in KD patients is typically continuous. It is reported to be either absent or less prominent or consistent in children younger than 1 year of age and older than 9 years of age. Eye findings include bilateral nonpurulent conjunctivitis, which is particularly prominent with fever. Other inflammatory eye findings including asymptomatic uveitis have been reported. Rash of all types can be associated with KD. The rash is also more prominent with fever. Frequently it is confluent in the diaper area and axilla in the acute phase. Skin peeling classically starts on the fingertips in the subacute phase. Blisters are uncommon. Oral changes include dry, red, and cracked lips; prominent follicles of the tongue (strawberry tongue); and an oral anathema. Aphthous ulcers can be present, primarily when associated with a triggering herpes-group virus infection. Cervical lymphadenopathy is frequently asymmetric. The criteria state they should be 1.5 cm or greater. Nodes can be tender, and a secondary lymphadenitis can occur, which may require additional therapy. Hands and feet frequently appear puffy and erythematous.

Neurologic symptoms are common in children with KD. The majority of toddlers are extremely irritable. Often children are withdrawn, lethargic, and clingy or complain of headaches, in particular with fever. Transient hearing loss can be present in a significant number of patients, most commonly sensorineural hearing loss (20 to 35 dB). It may be related to salicylate toxicity in some children. Persistent hearing loss is rare.³³⁹

Other organ manifestations include acute arthritis,³⁴⁰ hepatitis,³⁴¹ gallbladder hydrops, intussusception, or pseudo-obstruction presenting as acute abdomen,³⁴² dysuria with sterile pyuria, genital swelling, and muscle pain and weakness.

Diagnosis and Diagnostic Tests. Inflammatory markers are commonly raised in children with KD. ESR and CRP, leukocytosis, anemia, mildly raised liver function tests, and low albumin levels are expected in children with acute KD.^{343,344} Laboratory markers are included in the AHA algorithm³²⁹ and have been used to predict adverse outcome.³⁴⁴

Because infections are commonly found in children with KD, an infectious workup is mandatory to detect concurrent ongoing infections that may require additional therapy. Cardiac evaluation in KD patients includes a chest radiograph, electrocardiogram, and echocardiography. DeZorzi and associates defined body-surface area–adjusted standards (z scores) for coronary artery abnormalities on echocardiography.³⁴⁵ These scores have subsequently been used to establish a classification system for the entire spectrum of coronary artery abnormalities including aneurysms.³⁴⁶ Follow-up echocardiography is required at 2 weeks in children with evidence of coronary damage and at 6 weeks in all children because vascular disease commonly peaks at 2 to 4 weeks.³⁴⁷

A severe complication of KD is increasingly recognized: macrophage activation syndrome (MAS).³⁴⁸ Latino and co-workers reported 12 of 638 KD patients who developed clinical and laboratory features of MAS including hepatosplenomegaly, cytopenia in two or more cell lines, hyperferritinemia and elevated hepatic enzymes, hypertriglyceridemia and/or hypofibrinogenemia, increased D-dimers, and evidence of hemophagocytosis on biopsy (4/12). Early recognition of MAS and increased immunosuppression are crucial.

Treatment. The first-line treatment for children with KD is IVIG at a dose of 2 g/kg.³⁴⁹ In addition, high-dose acetylsalicylic acid (ASA) at 30 to 50 mg/kg or 80 to 100 mg/kg is frequently used as an antipyretic and anti-inflammatory drug while the child is febrile. However, a metaanalysis did not find sufficient evidence for ASA treatment in KD.³⁵⁰ Conceptually, there is strong support for the use of ASA in KD because IVIG and ASA were found to differentially modulate the expression of TNF and its downstream effects in the KD animal model.³⁵¹ Importantly, low-dose ASA has an antithrombotic effect by inhibiting the production of thromboxane A₂ and prostacyclin in platelets.

Recurrence of fever after a dose of IVIG is commonly treated with a repeat dose of IVIG.³⁵² Children with refractory KD, defined as failure to respond to IVIG retreatment commonly receive corticosteroid therapy. A trial exploring the efficacy of early corticosteroids for primary KD therapy in addition to IVIG did not demonstrate a significant benefit.³⁴⁹ In nonresponders TNF inhibitors have been used.^{353,354} Son and co-workers reported that patients treated

with infliximab had a faster resolution of fever and fewer days of hospitalization.³⁵⁵ Abciximab is a monoclonal antibody against glycoprotein (GP)IIb-IIIa on platelets. A small study of 18 children with KD and large coronary artery aneurysms suggested that abciximab treatment may be associated with improved vascular remodeling.³⁵⁶

Children with KD require cardiology follow-up at 6 weeks including clinical assessment and echocardiography. Commonly, low-dose ASA treatment is discontinued in all patients in whom the coronary artery lesions have resolved. Children with evidence of coronary disease at 6 weeks require long-term care. In many centers asymptomatic KD patients are reassessed at 12 months and then discharged.

Outcome. The 5-year survival of children with KD is excellent at greater than 99%.³¹⁸ However, one in 20 children with KD will develop permanent damage to their coronary arteries.^{357,358} Children may develop vascular aneurysms and stenoses beyond the coronary arteries (Figure 108-6). Early interventions including stenting or coronary bypass operations may be required.³⁵⁹ Even asymptomatic children with KD and aneurysms are at high risk of myocardial lesions.³⁶⁰ The long-term impact of “transient” coronary artery dilatations/ectasia remains to be determined.³⁶¹ KD may lead to endothelial dysfunction and premature arteriosclerosis.³⁶² The psychosocial impact of KD was recently explored: Parents of KD patients report significant distress and anxiety even years after the acute illness.³⁶³

Polyarteritis Nodosa

Polyarteritis nodosa (PAN) is a rare necrotizing vasculitis of medium-sized vessels.^{321,364} The focal/segmental, transmural necrosis can lead to aneurysm formation. Classically lesions heal and scar with a palpable fibrotic nodule (nodosa). The

Figure 108-6 Giant aneurysms in a 6-month-old girl with Kawasaki disease. Gadolinium-enhanced, reconstructed magnetic resonance imaging angiography demonstrates multiple irregular aneurysms of the coronary arteries, the brachial and subclavian arteries, and both common iliac arteries and internal iliac arteries.

classic or systemic form can affect medium-sized arteries in multiple organs and typically presents with clinical and laboratory features of severe systemic inflammation. In contrast, cutaneous PAN is limited to the medium-sized arteries of the skin. It is more common and is characterized by periodic exacerbations often associated with *Streptococcus* infection.³²¹

Definition and Classification. The proposed EULAR/PreS-endorsed consensus criteria for (systemic) childhood PAN are shown in Table 108-8.²⁹⁶ The group modified the adult ACR PAN criteria by making biopsy evidence of necrotizing vasculitis or angiographic abnormalities a mandatory criterion.

The sensitivity as determined in the validation process described earlier was 89.6%, and the specificity was 99.6%. The mandatory criterion of biopsy evidence had the highest sensitivity and specificity (>80%). Peripheral neuropathy was the least sensitive (26%), and renal involvement was the least specific (37%) criterion.²⁹⁶ The consensus conference did not propose criteria for cutaneous PAN but recognized the need for a separate category.²⁵⁵ The disease characteristics were described as presence of subcutaneous nodular, painful, nonpruritic lesions with or without livedo reticularis with no systemic involvement except for myalgia, arthralgia, and nonerosive arthritis; biopsy evidence of necrotizing, nongranulomatous vasculitis; negative tests for ANCA; and an association with streptococcal infections.²⁵⁵

Epidemiology. Systemic PAN is a rare disease. The overall incidence is estimated at 2 to 9 per million³⁶⁵ and varies among ethnicities.³²¹ In a recent 5-year survey of all childhood vasculitis at 15 Turkish centers, PAN accounted for only 6% of cases. An association of systemic PAN with familial Mediterranean fever (FMF) was suggested.³⁶⁶ Associations with hepatitis B and other viruses with childhood PAN have been reported.³²¹

In 2004 an international PAN survey of 22 pediatric centers identified 110 children, of whom 63 children (57%) had systemic PAN and only 33 (30%) had cutaneous PAN.³⁶⁴ However, in many centers the number of children with cutaneous PAN is significantly higher than with systemic PAN. The association of cutaneous PAN with medications and systemic inflammatory/autoimmune diseases has been reported.³⁶⁷⁻³⁶⁹

Clinical Presentation. Systemic inflammation often presents as fevers, fatigue, and weight loss in children with systemic PAN.³²¹ Decreased perfusion through medium-sized vessels can cause focal organ ischemia including severe abdominal pain,³⁷⁰ cardiac ischemia, muscle pain, skin infarction with gangrene, livedo reticularis, and renal hypertension. The severe focal vessel inflammation can present as cutaneous painful nodules often located on the calves or feet, focal muscle pain, peripheral or cranial neuropathy, and inflammatory CNS lesions among others.^{321,371} Necrotizing vascular inflammation in systemic PAN can lead to fragility of the medium-sized arterial vessel wall and significant hemorrhage.³⁷² Renal disease in systemic PAN is classically renal hypertension due to segmental artery disease; however, small vessel involvement presenting as isolated proteinuria, nephritic or nephrotic syndrome, and renal failure are reported in a series of 26 children from Turkey.³⁷³

Cutaneous PAN is characterized by the presence of deep skin nodules predominantly on the lower legs, which are frequently found at different stages of development. Most commonly a violaceous color or pigmentation with retiform appearance persists for months (Figure 108-7A-C). Ulceration can be a complication. Pain, arthralgias/arthritis, malaise, and moderate fever are associated symptoms in children with cutaneous PAN.³⁷⁴

Diagnosis and Diagnostic Tests. Inflammatory markers including ESR and CRP are commonly raised in children with active systemic and cutaneous PAN.³²¹ Organ function parameter may be abnormal. Specific diagnostic markers for PAN are not available. Characteristic PAN skin biopsy features are identical to adult PAN (see Chapter 90). Characteristic angiography findings include aneurysms and stenoses of the medium-sized arteries.³²¹

Treatment. The treatment of childhood systemic PAN is based on adult studies and recommendations and is summarized in Chapter 90.³¹³ Pediatric case reports and series supported the efficacy of corticosteroids, combination immunosuppression, and biologic therapies including TNF inhibitors and B cell depletion using rituximab.^{316,321,371,373} Addition of antiplatelet agents may be required. Children with cutaneous PAN are commonly treated with nonsteroidal anti-inflammatory medication or corticosteroids. Refractory patients require immunosuppressive combination therapy. Prophylactic antibiotics are considered in children with evidence of *Streptococcus* infections.³²¹

Outcome. The 1-year and 5-year survival rates of 26 Turkish children with systemic PAN was only 72.5% and 60%, respectively.³⁷³ This is significantly worse than outcomes described by Ribi and colleagues of adult PAN 1-year and 5-year survival rates at 99% and 92%, respectively.³⁷⁵ However, Phillip and Luqmani reported a 5-year survival rate of 75% to 80% in a recent systematic review.³¹⁸ Relapses are common in adults with PAN: Pagnoux reported 5-year relapse-free survival rates of only 59%; 86 patients (25%) died during the study interval of almost 6 years. In contrast, cutaneous PAN appears to have a good prognosis. No prospective long-term data are available for childhood PAN.

Large Vessel Vasculitis

Takayasu's arteritis (TA) is the most common childhood large vessel vasculitis.³⁷⁶ Histologically, TA is indistinguishable from giant cell arteritis (GCA) in adults. TA and GCA may represent a disease spectrum rather than different entities.^{377,378} Both diseases are characterized by giant cells, which represent multinuclear cells formed by fusion of monocytes/macrophages and in TA can be found in the wall of large vessels including the aorta and its major branches.

Definition and Classification

The proposed EULAR/PreS-endorsed consensus criteria for TA are shown in Table 108-8.²⁹⁶ Angiographic abnormalities are a mandatory criterion. In addition, at least one of five criteria including pulse deficit or claudication, blood pressure discrepancy of greater than 10 mm Hg, bruits, hypertension, or elevated acute-phase reactant has to be present. The sensitivity and specificity as determined in the

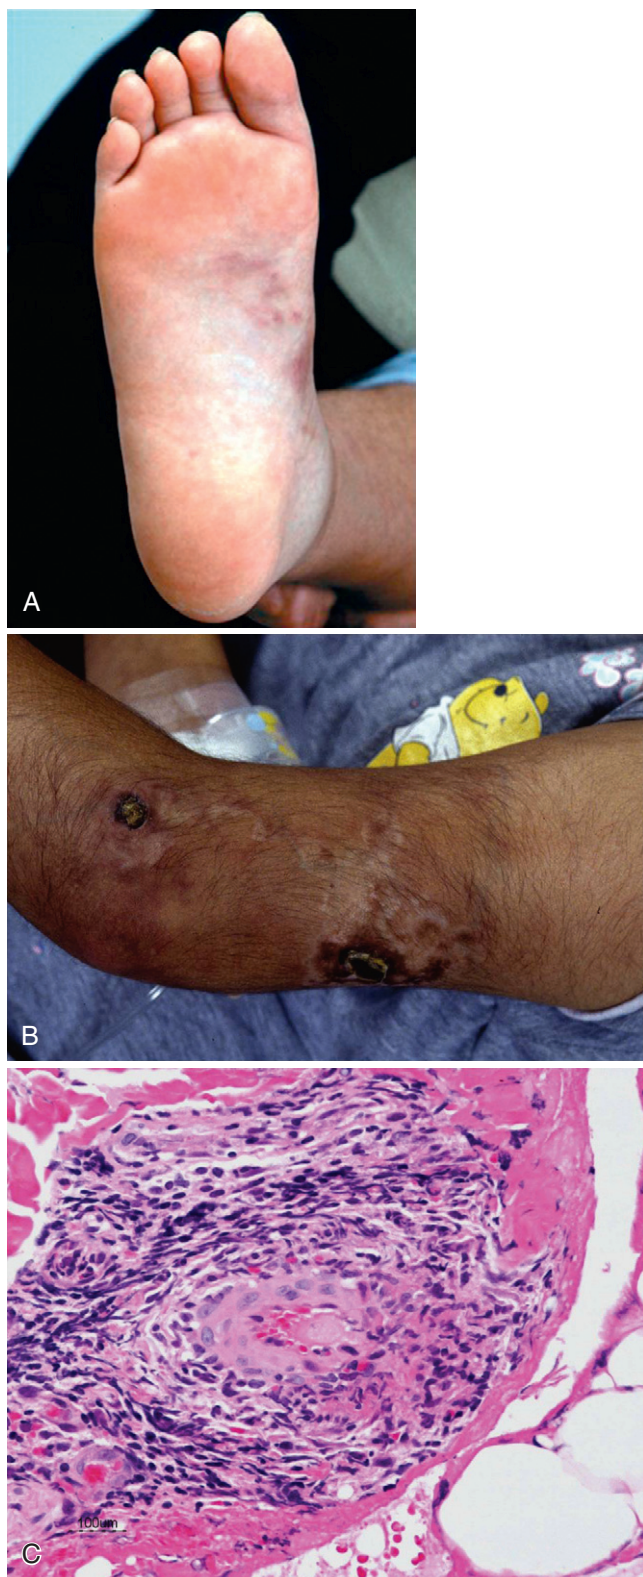

Figure 108-7 Nodular skin lesions in a 16-year-old girl with cutaneous polyarteritis nodosa. Painful subcutaneous nodules on the sole of the foot of a child with active cutaneous polyarteritis nodosa. Some nodules have evolved into purple lesions appearing like bruises. New lesions are pink and tender (A). Healed and crusted lesions on the elbow at a later stage of illness (B). Hematoxylin-eosin staining of a skin nodule demonstrating the segmental necrotizing inflammation, with fibrin deposits and disruption of the arterial vessel wall integrity (C).

validation process described earlier were 100% and 99.9%, respectively.²⁵⁷

Epidemiology

The incidence of adult TA was recently reported at 0.8 per million in the United Kingdom.³⁷⁹ It may vary between ethnicities with higher incidences in Asia,^{380,381} Africa,³⁸² and Latin America.³⁸³ No population-based pediatric data are available; however, children may account for up to 30% of patients in some studies.³⁸⁴⁻³⁸⁶ Most commonly, childhood TA is diagnosed in adolescence. All series have a female predominance ranging from 14:1 to 1.4:1. Recent case series reported a total of 99 children with TA.^{382,387-389} Associations of *Mycobacterium tuberculosis* and TA have consistently been suggested.³⁹⁰

Clinical Presentation

Children with TA often present with clinical signs of organ ischemia and systemic inflammation. Most commonly, headache or associated neurologic deficits such as strokes, seizures or syncope, chest or abdominal pain, claudication of extremities, fever, and weight loss are the presenting symptoms.^{387,388} Examination frequently reveals hypertension, absent pulses, and bruits.

Diagnosis and Diagnostic Tests

The diagnosis of TA is based on clinical pattern recognition and confirmation by angiography. Inflammatory markers including CRP and ESR have limited sensitivity for active TA³⁹¹; no disease-specific markers have been identified. Hoffman and Ahmed demonstrated that there is a poor correlation between serum markers and vascular histopathology in adult TA.³⁹² Angiography is the cornerstone of diagnosing and monitoring TA (see Figure 108-8A,B). Inflammatory arterial wall disease presents as arterial wall thickening, vessel stenosis, occlusion, or rarely aneurysms.³⁹³ Different vascular imaging modalities are used in TA, each with distinct advantages and limitations.^{394,395} Conventional angiography provides information about blood flow, perfusion pattern, collateralization, and degree of vessel stenosis. It reliably identifies clots or low-flow vessel segments posing a risk for subsequent artery to artery embolisms. Magnetic resonance angiography (MRA) is noninvasive and provides information about the characteristics of the vessel wall including thickening, contrast enhancement, and surrounding soft tissue inflammation.³⁹⁶ CT angiography may provide similar information as MRA; however, the associated radiation exposure often limits its use in children. Recent studies highlighted the utility of 18F-fluorodeoxyglucose (18FDG) positron emission tomography scan.³⁹⁷ Doppler ultrasound correlates well with angiography in delineating homogenous wall thickening in the aorta and its branches. It may be a promising tool for childhood TA.³⁹⁸

Treatment

Corticosteroids are the cornerstone of medical TA treatment in adults and children.³¹⁴ Combination

Figure 108-8 Angiographic progression of Takayasu arteritis in a 6-year-old girl. Gadolinium-enhanced, reconstructed magnetic resonance angiography (MRA) demonstrates a critical superior mesenteric artery stenosis at diagnosis of Takayasu arteritis in a 6-year-old girl (A). Nine months later the repeat MRA demonstrates significant progression despite high-dose immunosuppressive treatment (B).

immunosuppression with cyclophosphamide was found to be effective in controlling disease activity in childhood TA.^{388,399} MTX was suggested in adult TA studies. Refractory childhood TA has been successfully treated with biologic therapies, primarily TNF inhibitors.⁴⁰⁰

Surgical treatment includes stenting, dilatation, and bypass surgery.³⁸⁸ Corresponding to adult TA recommendations, the best time for vascular intervention in children is in inactive disease.⁴⁰¹ A close collaboration between all treating subspecialties is mandatory.

Outcome

The overall outcome of TA is poor. The 5-year survival rate was reported to be 70% to 93%.³¹⁸ Maksimowicz-McKinnon and colleagues gave a guarded prognosis of 93% attaining remission but only 28% having sustained remission of at least 6 months' duration after prednisone was tapered to less than 10 mg daily. Angioplasty and vascular surgery were initially successful. Restenosis occurred in 78% of angioplasty and 36% of bypass/reconstruction procedures. More than two-thirds of TA patients had difficulty performing routine daily activities, and one-fourth were unable to work.⁴⁰² Jales-Neto and co-workers recently determined that patients with childhood-onset TA had a significantly lower frequency of disease remission compared with adult-onset TA (24% vs. 56%) and more aneurysms (41% vs. 11%).⁴⁰³

Central Nervous System Vasculitis

Childhood CNS vasculitis is an increasingly recognized inflammatory brain disease.⁴⁰⁴ CNS vasculitis is classified as

secondary, when it occurs in association with a systemic illness including infection, malignancy, or rheumatic disease such as a systemic vasculitis (Table 108-9). Childhood primary CNS vasculitis solely affects the vessels of the brain and spinal cord.

Definition and Classification

The diagnosis of childhood primary CNS vasculitis is based on the modified Calabrese criteria for primary angiitis of the CNS (PACNS), which mandate (1) a newly acquired focal or diffuse neurologic deficit or a psychiatric manifestation in a patient 18 years of age or younger and (2) angiography and/or brain biopsy evidence of CNS vasculitis in the absence of a systemic underlying condition known to cause or mimic CNS vasculitis.^{404,405} Childhood PACNS (cPACNS) is further subdivided into angiography-positive cPACNS and angiography-negative, small vessel cPACNS (SVcPACNS), with the latter being confirmed on elective brain biopsies.^{404,406}

Epidemiology

The incidence of childhood CNS vasculitis is unknown. New clinical phenotypes continue to be recognized: Angiography-positive CNS vasculitis was found to be the underlying process in a large subgroup of vascular strokes, a condition neurologists may diagnose as transient cerebral arteriopathy (TCA).^{406,407} Recently, new clinical phenotypes of cPACNS have been described including refractory seizure status, movement disorder, and optic neuritis.^{408,409} Children with cPACNS may be diagnosed as "atypical" demyelinating disease.

Table 108-9 Classification of Childhood Primary and Secondary Central Nervous System (CNS) Vasculitis

Childhood Primary CNS Vasculitis (cPACNS)
Angiography-positive, nonprogressive cPACNS (NPcPACNS)
Angiography-positive, progressive cPACNS (PcPACNS)
Angiography-negative, small vessel cPACNS (SVcPACNS)
Secondary CNS Vasculitis in Children
Infection or postinfectious
Bacterial infection
<i>Mycobacterium tuberculosis</i>
<i>Mycoplasma pneumoniae</i>
<i>Streptococcus pneumoniae</i>
<i>Treponema pallidum</i>
Spirochete infection
<i>Borrelia burgdorferi</i>
Viral infection
Cytomegalovirus
Enterovirus
Epstein-Barr virus

Microscopic polyarteritis
Granulomatosis with polyangiitis
Inflammatory bowel disease
Hemophagocytic
Lymphohistiocytosis
Mitochondrial diseases
Drug-induced central nervous system vasculitis
Hemoglobinopathies
Malignancy
Radiation

Clinical Presentation

Children with cPACNS can present with any focal or diffuse neurologic deficits or psychiatric symptoms. Children with angiography-positive disease typically present with headaches and strokes including acute hemiparesis, facial droop, hemisensory deficits, fine motor deficits, or dysphasia. Additional seizures and severe cognitive dysfunction are more commonly seen in progressive cPACNS.⁴⁰⁶

Children with angiography-negative small vessel cPACNS may present with systemic features including fever, malaise, and flulike symptoms, associated with headache, neurocognitive dysfunction, behavior changes, or intractable seizures. Focal neurologic deficits, optic neuritis, and myelitis can be presenting features. Previously healthy children may have developed a rapid neurologic

deterioration and present with an acute encephalitis or may have had subacute progression of symptoms such as worsening seizures or behavior changes over weeks to months.⁴⁰⁴

Diagnosis and Diagnostic Tests

The suspected diagnosis of cPACNS mandates a thorough evaluation. Systemic illnesses and other inflammatory and noninflammatory brain diseases have to be considered.⁴⁰⁴ A diagnostic algorithm was recently proposed (Figure 108-9). Inflammatory markers can be elevated in children with cPACNS, most commonly in the small vessel subtype. Von Willebrand factor antigen appears to correlate with clinical disease activity. Cerebrospinal fluid (CSF) analysis frequently reveals a mild pleocytosis with predominantly lymphocytes and occasionally elevated CSF protein. Frequently the opening pressure is raised.

The absence of laboratory markers does not exclude cPACNS. In fact, children with angiography-positive, nonprogressive cPACNS frequently have normal inflammatory markers. In contrast, angiography-positive progressive cPACNS and small vessel cPACNS patients commonly present with laboratory signs of inflammation. Serial testing may be required. Oligoclonal banding is found in children with confirmed small vessel cPACNS.⁴⁰⁹

MRI studies identify ischemic, diffusion-restricted lesions and inflammatory, fluid-attenuated inversion recovery (FLAIR)-positive parenchymal lesions.⁴¹⁰ MRA and conventional angiography characterize vascular stenoses^{411,412} (Figure 108-10A,B). Gadolinium-enhanced MRA sequences can demonstrate vessel wall enhancement and thickening in more than 85% of adult and pediatric patients with active cPACNS.⁴¹³

Brain biopsies confirm the diagnosis of angiography-negative cPACNS⁴⁰⁹ (Figure 108-11). In contrast to adults, biopsies are not required in children with angiography-positive disease because the diagnosis is not confounded by arteriosclerosis. Elective brain biopsies can be lesional as determined by MRI or nonlesional in the nondominant hemisphere.⁴⁰⁹ The diagnostic yield is greater than 90% in

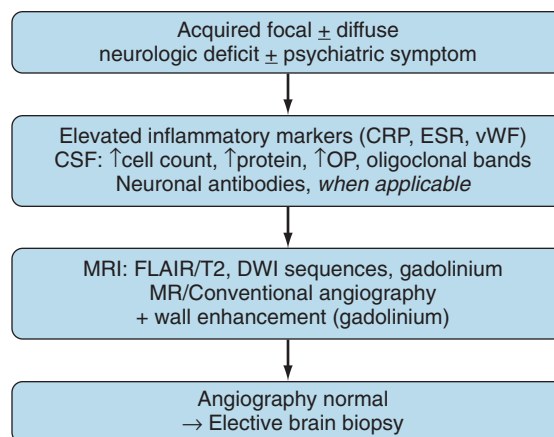

Figure 108-9 Proposed diagnostic algorithm for children with suspected central nervous system vasculitis. CSF, cerebrospinal fluid; CRP, C-reactive protein; DWI, diffusion-weighted imaging; ESR, erythrocyte sedimentation rate; FLAIR, fluid-attenuated inversion recovery; MR, magnetic resonance; MRI, magnetic resonance image; OP, opening pressure; vWF, von Willebrand factor.

children. Nondiagnostic biopsies are most commonly found when inadequate specimens are obtained.⁴⁰⁹

The differential diagnosis of childhood CNS vasculitis includes nonvasculitic inflammatory brain diseases such as neuronal autoantibody-mediated disease and demyelinating diseases. Neuronal autoantibodies should be tested when clinically indicated. In addition, noninflammatory vasculopathies have to be considered.⁴⁰⁴

Treatment

No randomized controlled trials are available for CNS vasculitis in adults and children. A recent prospective observational cohort study evaluated the efficacy and safety of a

Figure 108-10 Primary, angiography-positive childhood central nervous system (CNS) vasculitis in an 8-year-old boy. Serial magnetic resonance angiography demonstrates severe stenosis of the right middle cerebral artery at diagnosis of CNS vasculitis (**A**). Immunosuppressive therapy led to excellent revascularization of the stenosed vessel and neurologic recovery of the child at the 12-month follow-up (**B**).

Figure 108-11 Primary, angiography-negative childhood central nervous system vasculitis in a 6-year-old girl. The elective, nonlesional brain biopsy demonstrates a lymphocytic vasculitis of the small muscular arteries. The intramural lymphocytic infiltrate consists of predominantly helper T cells (hematoxylin-eosin staining, magnification $\times 400$).

24-month induction-maintenance protocol for small vessel cPACNS,⁴¹⁴ demonstrating a full neurologic recovery in two-thirds of children. Case reports and series describe the efficacy of other immunosuppressive treatments for different types of cPACNS.⁴¹⁵⁻⁴¹⁷ In children with nonprogressive cPACNS, adjunctive corticosteroids may prevent recurrent ischemic events and improve neurologic outcome.

Outcome

There is limited information about the long-term outcome of children with CNS vasculitis. In angiography-positive cPACNS, two-thirds have a monophasic, nonprogressive course. These children often present with large ischemic lesions due to proximal large vessel stenosis and ischemia in the vascular territory. Although progression of inflammation and involvement of other vascular beds is limited in this group, the associated neurologic deficit often exceeds the other subtypes characterized by progression of inflammation. Inflammation is reversible when recognized and treated early, as recently demonstrated in the small vessel cPACNS study.⁴¹⁴ Disease flares are seen in a significant number of patients. Prospective collaborative studies are ongoing to further characterize the long-term outcome of children with CNS vasculitis worldwide.

Bacterial Arthritis

PAUL P. COOK • DAWD S. SIRAJ

KEY POINTS

Acute bacterial arthritis is a medical emergency that warrants rapid, accurate diagnosis and immediate treatment along with appropriate consultation with additional specialists as needed.

Most instances of native joint infection are the result of bacteremic seeding.

Staphylococcus aureus is the most frequent microorganism in adult nongonococcal septic arthritis.

The initial selection of an antibiotic regimen should be broad enough to take into account host factors, clinical characteristics, likely causative microorganisms, and regional antibiotic sensitivity data pending confirmation of bacteria by culture and sensitivities.

An infected joint must be adequately drained, and an antibiotic course that is sufficiently long to cure the infection must be instituted. Surgical drainage should be considered, but only if needle aspirations are unsuccessful or impractical.

Poor prognostic factors in bacterial joint infection include old age, underlying rheumatoid arthritis, and infection in a prosthetic joint.

Débridement, antibiotics, and implant retention (DAIR) is a reasonable option for selected patients with early prosthetic joint infections.

Late prosthetic joint infections require antibiotic treatment directed at the isolated microorganism and the complete removal of the infected prosthesis before reimplantation of a new prosthesis in a one-stage or two-stage operation.

Reducing the risk of a prosthetic joint infection involves a thorough preoperative evaluation, perioperative use of antibiotics, and the careful use of antibiotic prophylaxis when a patient with a prosthesis is exposed to transient bacteremia; clinical evidence does not support the use of antibiotic prophylaxis for most dental procedures.

EPIDEMIOLOGY

Bacterial infections of the joint are usually curable with treatment, but morbidity and mortality are still significant in patients with underlying rheumatoid arthritis (RA), patients with prosthetic joints, elderly patients, and patients who have severe and multiple comorbidities. Goldenberg¹ wrote in 1994, "Treatment and outcome [of septic arthritis] have not improved substantially over the past 20 years." This statement is probably still true today. Incremental knowledge of the pathogenesis of septic arthritis caused by two common organisms, *Neisseria gonorrhoeae* and *Staphylococcus aureus*, and understanding of the pathobiology of prosthetic devices may lead to innovations in the management and prevention of bacterial joint infections.

The normal diarthrodial joint is resistant to bacterial infection because of local and systemic host defenses. Bacteria can reach the synovial-lined joint, however, via the hematogenous route and result in septic arthritis. The large joints are affected more commonly than the small joints, and monoarticular infection is the rule, with polyarticular infection (more than one joint involved) in less than 20% of cases. A prospective series from a community-based population in the Netherlands reflected a representative distribution of joint involvement: knee 55%, ankle 10%, wrist 9%, shoulder 7%, hip 5%, elbow 5%, sternoclavicular joint 5%, sacroiliac joint 2%, and foot joint 2%.²

The incidence of septic arthritis ranges from 2 to 5/100,000/year in the general population, 5.5 to 12/100,000/year in children, 28 to 38/100,000/year in patients with RA, and 40 to 68/100,000/year in patients with joint prostheses.^{3,4} The incidence appears to be increasing, probably related to orthopedic procedures, an aging population, and the increased use of immunosuppressive therapy.⁵ The organisms causing bacterial arthritis depend on the epidemiologic circumstances (Table 109-1). Monoarthritis of a prosthetic joint in an elderly man is likely due to *Staphylococcus*, whereas a migratory arthritis in a sexually active woman with skin lesions is likely due to disseminated gonococcal infection. Septic arthritis caused by methicillin-resistant *S. aureus* (MRSA) is common in the elderly, in persons who use intravenous drugs, and in individuals with prosthetic joints.⁶

Table 109-1 Organisms Causing Joint Infection in Various Hosts

Adults	Children ≤5 yr old	Children >5 yr old	Neonates	Prosthetic
Common <i>Staphylococcus aureus</i> <i>Streptococcus pneumoniae</i> β-Hemolytic streptococci (mainly Lancefield groups A, G, and B) <i>Neisseria gonorrhoeae</i> (adult and sexually active adolescent) Enterobacteriaceae (age > 60 or predisposing condition) <i>Salmonella</i>	Common <i>S. aureus</i> <i>Haemophilus influenzae</i> * Group A streptococci <i>S. pneumoniae</i>	Common <i>S. aureus</i> Group A streptococci	Common <i>S. aureus</i> Group B streptococci Enterobacteriaceae	Common Coagulase-negative staphylococci <i>S. aureus</i>
Rare <i>Pseudomonas</i> <i>Mycobacterium tuberculosis</i> <i>H. influenzae</i> <i>Neisseria meningitidis</i> <i>Pasteurella</i> Anaerobes <i>Mycoplasma/Ureaplasma</i> Fungi (<i>Sporothrix</i> , dimorphic fungi, <i>Cryptococcus</i>) <i>Borrelia burgdorferi</i>	Rare <i>Salmonella</i> <i>H. influenzae</i> <i>N. meningitidis</i> <i>N. gonorrhoeae</i> <i>Kingella kingae</i> <i>M. tuberculosis</i> <i>B. burgdorferi</i>	Rare <i>N. meningitidis</i> <i>N. gonorrhoeae</i> <i>K. kingae</i> <i>M. tuberculosis</i> <i>B. burgdorferi</i>	Rare <i>Pseudomonas</i> <i>H. influenzae</i> <i>N. gonorrhoeae</i>	Less Common <i>Corynebacterium</i> Enterococci and streptococci <i>Pseudomonas aeruginosa</i> Enterobacteriaceae <i>Propionibacterium</i> Other anaerobes <i>Candida</i> <i>M. tuberculosis</i>

*Rare in children immunized with Hib vaccine.

Modified from Atkins BL, Bowler IC: The diagnosis of large joint sepsis, *J Hosp Infect* 40:263–274, 1998.

ETIOLOGY

Most cases of septic arthritis result from hematogenous seeding of the synovial membrane. The abundant vascular supply of the synovium and the lack of a limiting basement membrane allow organisms to target joints during bacteremia. Less common causes of septic arthritis include direct inoculation after joint aspiration or corticosteroid injection of a joint; animal or human bites; nail puncture wounds or plant thorn injury; joint surgery, especially hip and knee arthroplasties; and spread by contiguous osteomyelitis, cellulitis, or septic bursitis.

Table 109-1 lists the common organisms that cause joint infections according to the age of the patient and whether the joint is native or prosthetic.⁵ Overall, *S. aureus* is the most common etiologic agent among children of all age groups, followed by group A streptococci and *Streptococcus pneumoniae*.⁷ Neonates and infants younger than 2 months old are more susceptible to group B streptococci and gram-negative enteric bacilli than older children. Rarely, *Pseudomonas*, *N. gonorrhoeae*, and *Candida albicans* may be responsible in very young children. Since the introduction of the *Haemophilus influenzae* type B vaccine, the incidence of septic arthritis caused by *H. influenzae* has declined dramatically.⁸ In sexually active adolescents, *N. gonorrhoeae* must be considered. *Pseudomonas aeruginosa* and *Candida* are potential pathogens in adolescent intravenous drug abusers. Patients with sickle cell anemia are prone to develop *Salmonella* arthritis, and immunocompromised children are at higher risk for infection with gram-negative bacilli. Other unusual joint pathogens in children include *Neisseria meningitidis*, anaerobes, *Brucella*, and *Kingella kingae*.

The organisms causing nongonococcal septic arthritis in adults are 75% to 80% gram-positive cocci and 15% to 20% gram-negative bacilli.⁹ *S. aureus* is the most common organism in native and prosthetic joint infections.

Staphylococcus epidermidis is common in prosthetic joint infections but is a rare cause of native joint infections. The streptococci including *Streptococcus pneumoniae* are the next most common group of gram-positive aerobes. *Streptococcus pyogenes* is followed by groups B, G, C, and F in frequency. Patients with non-group A streptococcal disease often have comorbidities such as immunosuppression, diabetes mellitus, malignancy, and severe genitourinary or gastrointestinal infections.¹⁰ Group B streptococcal arthritis in adults is uncommon, but it can be a serious infection in adult diabetics and patients with late prosthetic hip infections.¹¹ Aggressive polyarthritis caused by group B streptococci may result in serious functional damage and permanent morbidity.¹² Patients predisposed to gram-negative bacillary infections include patients with a history of intravenous drug abuse, very young and very old patients, and immunocompromised patients.¹³ The most common gram-negative organisms are *Escherichia coli* and *P. aeruginosa*.

Anaerobes account for 5% to 7% of septic arthritis.^{2,3,14} Common anaerobes include *Bacteroides*, *Propionibacterium acnes*, and various anaerobic gram-positive cocci. Predisposing factors include wound infections, joint arthroplasty, and immunocompromised hosts. Foul-smelling synovial fluid or air in the joint space should raise the suspicion of anaerobic infection, and appropriate cultures should be obtained and held for at least 2 weeks. Anaerobes and coagulase-negative staphylococci are more common in prosthetic joint infections.

Polyarticular septic arthritis is much less common than monoarticular infection.¹⁵ Many of the patients have one or more comorbidities, and some have been intravenous drug abusers. Occurrence of polyarticular septic arthritis is high in patients with RA and averages 25% (range, 18% to 35%).¹⁶ Although *S. aureus* is the most common pathogen, group G streptococci, *H. influenzae*, *S. pneumoniae*, or mixed aerobic and anaerobic bacteria have been responsible

for polyarticular infections. Involvement of more than one joint also can occur in certain patient populations such as neonates and patients with sickle cell anemia, or with certain organisms, such as *N. gonorrhoeae*, *N. meningitidis*, and *Salmonella*.¹⁷

Polymicrobial (two or more bacterial species), polyarticular (two or more joints) septic arthritis is a rare clinical entity.¹⁸ Large joints are usually affected. Among five reported cases, the knee was affected in four cases (bilaterally in two); the elbow and wrist were affected in three cases, and the shoulder was affected in two cases. The mean number of joints infected was three. Bacteremia was present in all but one case (80%) and always involved the same organisms that were in the synovial fluids. Most bacterial species isolated were the usual organisms seen in septic arthritis. Combinations of gram-positive aerobic and anaerobic organisms were common. A characteristic of most cases (80%) was the extension of locally destructive processes as a result of the contiguous spread of infection from the affected joints such as osteomyelitis, fasciitis with compartment syndrome, and abscess or sinus tract formation. Systemic complications including septic shock, multiorgan failure, and toxic shock syndrome were noted in 60% of cases. The mortality rate of polymicrobial, polyarticular septic arthritis in this small series was 60%.¹⁸

Arthrocentesis is a common procedure frequently used in conjunction with corticosteroid administration in patients with various forms of joint diseases. Septic arthritis after joint aspiration and injection is extremely rare, occurring in 0.0002% of patients.¹⁹ Arthroscopic surgery is also a common procedure that is complicated by a low incidence of septic arthritis (<0.5% of procedures).²⁰ Coagulase-positive and coagulase-negative staphylococci account for more than 87% of these infections. In rare cases of septic arthritis of the knee related to anterior cruciate ligament repair, the tissue allografts were identified as the source of the infection.²¹ Cultures yielded gram-negative organisms such as *Pseudomonas aeruginosa*, *Citrobacter*, *Klebsiella oxytoca*, and mixed infection with *S. aureus*, *Enterococcus faecalis*, and *P. aeruginosa*.

PATHOGENESIS

Acute bacterial arthritis is usually designated gonococcal or nongonococcal. In the case of gonococcal arthritis, *N. gonorrhoeae* possesses a variety of virulence factors on the cell surface. *N. gonorrhoeae* is able to attach to cell surfaces via filamentous outer-membrane appendages, or pili. Another outer membrane protein, protein I, has forms IA and IB. Protein IA binds the host factor H and inactivates complement component, C3b, circumventing the host's complement system.²² Protein IA also prevents phagolysosomal fusion in neutrophils, enabling survival of the organism within the phagocytes. Lipo-oligosaccharide is a gonococcal molecule similar to lipopolysaccharide of other gram-negative bacteria and possesses endotoxin activity, which contributes to the joint damage seen in gonococcal arthritis.²³

S. aureus is the most common organism that causes nongonococcal arthritis. The virulence of *S. aureus* is associated with its ability to attach to host tissue within the joint, evade host defenses, and cause damage to the joint.

Table 109-2 Virulence Factors of *Staphylococcus aureus* and Their Mechanisms of Action

Virulence Factor	Mechanism of Action
Collagen-binding protein	Binds collagen
Clumping factor A and B	Binds fibrinogen
Fibronectin-binding protein	Binds fibronectin
A and B	
Capsular polysaccharide	Antiphagocytic
Protein A	Binds fragment crystallizable portion of IgG
Toxic shock syndrome toxin-1	Superantigen
Enterotoxins	Superantigens

Table 109-2 lists some of these virulence factors and their mechanisms of action. The attachment of *S. aureus* to the joint tissues is facilitated by microbial surface components recognizing adhesive matrix molecules (MSCRAMMs). MSCRAMMs are embedded in the cell wall peptidoglycan of *S. aureus* (Figure 109-1).²⁴ They bind to host matrix proteins including collagen, fibrinogen, elastin, vitronectin, laminin, and fibronectin. Gene knockout experiments in animal models showed that the gene coding for the protein that binds collagen is an important virulence factor for *S. aureus* joint infections.²⁵ Most *S. aureus* isolates also express the fibronectin-binding proteins, FnbpA and FnbpB. Disruption of the respective genes, *fnbpA* and *fnbpB*, by knockout gene experiments completely obliterates adherence of *S. aureus* to fibronectin-coated surfaces (e.g., prosthetic joints).²⁶

The genes of several *S. aureus* cell surface proteins (e.g., protein A, fibronectin-binding proteins, coagulase) and

Figure 109-1 Schematic diagram of *Staphylococcus aureus*. Many of the cell surface proteins are regulated by the *agr* locus (see text). At low cell concentrations, *agr* facilitates the production of the cell-surface proteins, which facilitate attachment to tissue. At higher cell concentrations, as occurs with establishment of infection, *agr* downregulates production of the cell surface proteins and activates genes coding for exotoxins. TSST-1, toxic shock syndrome toxin-1.

exotoxins (e.g., toxic shock syndrome toxin-1 [TSST-1], enterotoxin B, proteases, and hemolysins) are regulated by the accessory gene regulator *agr*.²⁷ At low cell numbers such as at the time of infection, production of cell surface proteins for attachment to host tissues is facilitated by the *agr* gene. When the cells have attached to tissue or an orthopedic device and have passed from exponential to stationary phase of growth, *agr* represses the expression of genes coding for cell surface proteins and activates genes coding for exotoxins and tissue-destroying exoenzymes. Because of this complex effect on the different stages of infection, inhibitors of *agr* may reduce tissue destruction but enhance tissue colonization. This effect could have implications for chronic infections such as occur with prosthetic joints.

Adherence receptors may allow intracellular movement of *S. aureus* into host cells (e.g., osteoblasts, endothelial cells, neutrophils).²⁸ When internalized, the organism is protected from the host's immune system and from antimicrobial agents. After adherence to the joint tissue, the bacteria activate the host immune response. Opsonization and phagocytosis are key defenses to eradicate the organism. *S. aureus* possesses two virulence factors, protein A and capsular polysaccharide, which interfere with these defenses. Protein A interferes with binding of complement by binding to the fragment crystallizable (Fc) portion of IgG. Protein A has been termed a *superantigen* for B cells because 30% of human B cells show Fab-mediated binding of the protein A molecule.²⁹ Binding of protein A by B cells leads to activation and subsequently to depletion of B cells through apoptosis.³⁰ This process may have implications regarding the ability of the immune system to control infection with *S. aureus*. The gene coding for protein A had been experimentally disrupted, and joint infection caused by the altered strain in a mouse model resulted in less joint destruction than infection caused by the wild-type strain.³¹

Capsular polysaccharide interferes with opsonization and phagocytosis. Of the 11 reported capsule serotypes of *S. aureus*, types 5 and 8 account for 85% of clinical infections.³² The capsule of these two serotypes is thinner, which facilitates the attachment to host fibronectin and fibrin.³³ When attached to these host proteins, capsule production is upregulated to form a thicker capsule, which makes the bacteria more resistant to opsonization and phagocytosis. The thicker capsule can also conceal the highly immunogenic adherence proteins (MSCRAMMs).³⁴ A mutant of the type 5 capsule in a murine model had a lower rate of infection and resulted in less severe arthritis compared with mice infected with the wild-type strain.³⁵ A vaccine consisting of types 5 and 8 polysaccharide reduced *S. aureus* bacteremia by more than half in hemodialysis patients.³⁶ The duration of protection was approximately 40 weeks after a single vaccination.

S. aureus exotoxins (e.g., TSST-1 and enterotoxins) act as superantigens that bind to host major histocompatibility complex (MHC) class II molecules and T cell receptors, resulting in clonal expansion and activation of some T cells. This activation triggers the release of numerous cytokines including interleukin (IL)-2, interferon- γ , and tumor necrosis factor (TNF).³⁷ Induction of these cytokines results in systemic toxicity and joint damage. The stimulated T cells initially proliferate but later disappear, likely due to apoptosis, and result in immunosuppression.³⁸ Internalized

organisms that had been protected from this inflammatory response may cause fulminant or persistent infection. Mice injected with strains of *S. aureus* lacking TSST-1 and enterotoxins rarely develop arthritis; when arthritis is induced, it is much milder compared with arthritis in animals injected with the wild-type strain.³⁷ Vaccination of mice with a mutated, recombinant form of enterotoxin A devoid of superantigen function was associated with a significant reduction in mortality.³⁹

In response to bacterial infection of the joint space, the host releases a variety of cytokines and inflammatory mediators. Initially, IL-1 β and IL-6 are released into the joint space, leading to an influx of inflammatory cells. These neutrophils and macrophages engulf invading bacteria and release additional cytokines including TNF, IL-1, IL-6, and IL-8. Blocking TNF with a monoclonal antibody and IL-1 with an IL-1 receptor antagonist inhibited leukocyte infiltration into the joint by 80% in a rabbit model of *S. aureus*-induced arthritis when the cytokine inhibitors were given simultaneously with *S. aureus*.⁴⁰ When the same inhibitors were given 24 hours after infection, however, there was no effect on leukocyte infiltration, suggesting the crucial roles of TNF and IL-1 in the early stages of *S. aureus*-induced arthritis. Release of interferon- γ is associated with the influx of T cells, which occurs a few days after infection. In a mouse model of *S. aureus* septic arthritis, interferon- γ has been associated with a worsening of the severity of arthritis while protecting the animals from septicemia.⁴¹ The host's early cytokine response may aid the clearance of organisms and limit infection in the host. A late cytokine response may amplify the destructiveness of an established infection.

CLINICAL FEATURES

Acute bacterial arthritis is most commonly monoarticular. Polyarticular infection occurs in 5% to 8% of pediatric cases and in 10% to 19% of adult nongonococcal cases.⁴² The differential diagnosis of acute monoarthritis overlaps with many causes of polyarthritis because virtually any form of arthritis can initially manifest as a single swollen joint. The three main etiologies to consider when a patient presents with acute monoarticular arthritis are trauma, infection, and crystal-induced synovitis such as gout or pseudogout. Polyarticular septic arthritis is usually seen in patients with systemic inflammatory disorders such as the spondyloarthropathies, RA, systemic lupus erythematosus, and other connective tissue diseases or patients with overwhelming sepsis.^{15,43}

Disseminated gonococcal infection occurs in 1% to 3% of patients infected with *N. gonorrhoeae*. Gonococcal arthritis is the most common cause of acute monoarthritis in sexually active young adults. In the preantibiotic era, gonococcal arthritis was a well-recognized illness in neonates. Disseminated gonococcal infection is three times more common in women than men. Women are more commonly affected because they are more likely to have asymptomatic and untreated primary infections. Bacterial dissemination has been associated with intrauterine devices and has occurred during menstruation, pregnancy, and pelvic operation.⁴⁴

Table 109-3 Risk Factors for Development of Septic Arthritis

Age >80 yr ³
Diabetes mellitus ³
Presence of a prosthetic joint in the knee or the hip ³
Recent joint surgery ³
Skin infection ³
Previous septic arthritis ⁴³
Recent intra-articular injection ⁶
HIV or AIDS
Intravenous drug abuse
End-stage renal disease on hemodialysis
Advanced hepatic disease
Hemophilia with or without AIDS
Sickle cell disease
Underlying malignancy
Hypogammaglobulinemia (susceptible to <i>Mycoplasma</i> infections) ⁴⁵
Late complement-component deficiency (susceptible to <i>Neisseria</i> infections) ⁴⁴
Low socioeconomic status with high rate of comorbidities ⁴³

AIDS, acquired immunodeficiency syndrome; HIV, human immunodeficiency virus.

Patients with gonococcal joint disease typically present with one of two forms. The first form is characterized by fever, shaking chills, vesiculopustular skin lesions, tenosynovitis, and polyarthralgias. Blood cultures are frequently positive, whereas synovial fluid cultures are rarely positive. *N. gonorrhoeae* can be cultured from genital, rectal, and pharyngeal sites. Tenosynovitis of multiple tendons of the wrist, fingers, ankle, and toes is a unique feature of this form of disseminated gonococcal infection and distinguishes it from other forms of infectious arthritis. In the second form of gonococcal infection, patients have purulent arthritis, most commonly of the knee, wrist, or ankle, and more than one joint can be infected simultaneously. *N. gonorrhoeae* can frequently be cultured from the synovial fluid.⁴⁵

The classic presentation of nongonococcal septic arthritis is the acute onset of pain, swelling, and decreased range of motion in a single joint. Large joints are affected most commonly. In adults, the knee is involved in more than 50% of cases; hip, ankle, and shoulder infections are less common.⁴¹ In infants and small children, the hip is more often involved.⁴⁶ Patients with septic arthritis often have underlying illnesses and predispositions to infections. Many are immunocompromised; are intravenous drug abusers; have prosthetic joints; and have diseases such as neoplasia, renal failure, and RA. Table 109-3 lists the risk factors that predispose to septic arthritis.^{3,5,47}

Most patients with bacterial arthritis are febrile, although chills are unusual. Fever may be absent in elderly patients. In children, septic arthritis usually is accompanied by fever, malaise, poor appetite, irritability, and progressive reluctance to use the affected limb. Physical examination typically reveals warmth and tenderness of the affected joint, joint effusion, and limited active and passive range of motion. Septic arthritis among patients with RA has been a special challenge to clinicians because of the high incidence of infection and the poor outcome. Septic arthritis in patients with RA is associated with poor joint outcome and high mortality.^{42,48} In many cases, it is difficult to differentiate septic arthritis in a joint already affected by RA from rheumatoid flare. Whenever bacterial arthritis is suspected, the most important diagnostic procedure is arthrocentesis

and examination of the synovial fluid. For joints that are deep and more difficult to aspirate, ultrasound-guided or fluoroscopy-guided needle aspiration should be done.

DIAGNOSIS AND DIAGNOSTIC TESTS

Arthrocentesis and synovial fluid analysis should be performed for all patients who present with an inflamed joint. Normal joints contain a small amount of synovial fluid that is clear, is highly viscous, and has few white blood cells (WBCs). The protein concentration is approximately one-third that of plasma, and the glucose concentration is similar to that of plasma. Infected synovial fluid is usually purulent with an elevated leukocyte count typically greater than 50,000 WBC/mm³ and often exceeding 100,000 WBC/mm³ with polymorphonuclear cell predominance. Synovial fluid levels of glucose, lactate dehydrogenase, and total protein have limited value in the diagnosis of septic arthritis. Although a low synovial fluid glucose (<40 mg/dL or less than half the serum glucose concentration) and an elevated lactate dehydrogenase suggest bacterial infection, they are not sufficiently sensitive or specific for the diagnosis.⁴⁹ Figure 109-2 is an algorithm for synovial fluid analysis; Table 109-4 lists the differential diagnoses of septic arthritis and the known causes of pseudoseptic arthritis.⁵⁰

A definite diagnosis of bacterial arthritis can be made only by visualizing bacteria on a gram-stained smear or by culturing bacteria from the synovial fluid. In patients not previously treated with antibiotics, synovial fluid cultures are positive in 70% to 90% of cases of nongonococcal bacterial arthritis.^{5,51} Blood cultures are positive in 40% to 50% of cases of septic arthritis and are the only method of identifying the pathogen in about 10% of cases.^{52,53} Occasionally, an extra-articular site of infection offers a clue to the etiologic organism infecting the joint. Examples include septic arthritis in association with pneumococcal pneumonia, *E. coli* urinary tract infection, and cellulitis caused by staphylococci or streptococci. Gram-positive

Synovitis after injection of hyal

*Extremely inflammatory synovitis with negative culture is referred to as pseudoseptic arthritis. Typically, synovial fluid analysis shows ≥50,000 white blood cells (WBC)/mm³. Often the WBC count is >100,000 WBC/mm³.

Data from references 6, 52, 53.

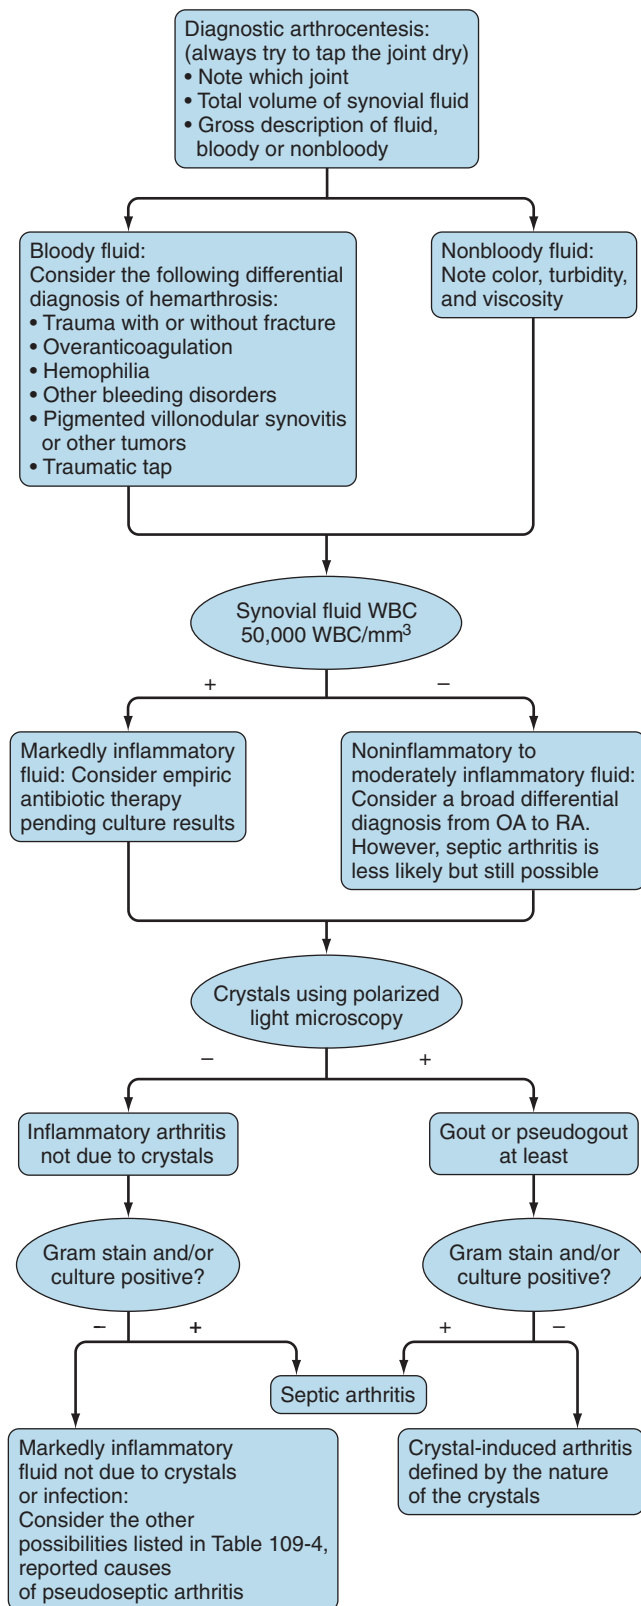

Figure 109-2 Algorithm for synovial fluid analysis in septic arthritis. OA, osteoarthritis; RA, rheumatoid arthritis; WBC, white blood cells.

cocci are identified in 50% to 75% of synovial fluid gram-stained smears, but gram-negative bacilli are identified less than 50% of the time in culture-proven cases.⁵¹

Inflammatory markers such as erythrocyte sedimentation rate (ESR), C-reactive protein (CRP), and WBC are usually raised, but the sensitivity is low and their absence does not exclude the diagnosis of septic arthritis.^{47,54} Serum and joint fluid procalcitonin levels as a marker of septic arthritis have been studied, but the results are inconclusive.⁵⁵ A study that evaluated neutrophil-derived circulating free deoxyribonucleic acid (j-cf-DNA) in synovial fluid of 42 patients found out that at a cutoff of 300 ng/mL, j-cf-DNA had a sensitivity of 89%, a specificity of 100%, a positive predictive value of 100%, and a negative predictive value of 97%.⁵⁶ If validated and standardized, this could be a valuable additional test to diagnose septic arthritis.

Culture for *N. gonorrhoeae* is almost always negative in skin lesions and is positive in less than 50% of synovial fluid samples and in less than one-third of blood cultures; this may be the result of the fastidious growth requirements of *N. gonorrhoeae*. The organism can often be easily recovered from other sites such as urethral, cervical, rectal, or pharyngeal specimens (i.e., the genitourinary tract). In culture-negative septic arthritis where *N. gonorrhoeae* is suspected, polymerase chain reaction techniques can be used to detect gonococcal DNA in the synovial fluid. Unfortunately, the technique is not standardized and is not widely available.⁵⁷

When culturing the synovial fluid, it should be brought directly to the laboratory and placed on conventional broth and solid media or into aerobic and anaerobic blood culture bottles. Inoculating blood culture bottles with 5 to 10 mL of joint fluid or smaller volumes into isolator tubes may increase the yield of positive cultures beyond that of standard techniques.^{58,59} Synovial fluid culture using the BACTEC Peds Plus/F bottle and the BACTEC 9240 instrument (Becton Dickinson Diagnostic Systems, Sparks, Md) detected significantly more pathogens and fewer contaminants than culture by the agar-plate method.⁶⁰

Plain radiographs in septic arthritis are usually normal early in the course of the infection, but baseline films should be obtained to look for evidence of other disease and contiguous osteomyelitis. Radiographs often show nonspecific changes of inflammatory arthritis including periarticular osteopenia, joint effusion, soft tissue swelling, and joint space loss. In more advanced infection, periosteal reaction, marginal or central erosions, and destruction of subchondral bone may be seen. Bony ankylosis is a late sequela of septic arthritis. Dislocation or subluxation of the femoral head is unique to hip infection of neonates.⁶¹

Ultrasound of the hip is the modality of choice to detect fluid collections in this deep joint and can serve as a guide in its aspiration. Ultrasound can be similarly used in other joints such as the popliteal cyst of the knee, shoulder, acromioclavicular, or sternoclavicular joints. Triple-phase bone scan using technetium 99m is often done in children to identify an associated metaphyseal osteomyelitis or avascular necrosis of the femoral head. Whole-body bone scan is preferred in young children because, despite focal symptoms, septic arthritis and osteomyelitis may be multifocal in this age group.⁶² In septic arthritis of all age groups, the periarticular distribution of increased uptake is seen on

the early “blood-pool” phase and the delayed images of the joint. Bone scans provide only nonspecific information, however, and cannot differentiate septic from noninfectious causes of joint inflammation. Bone scans are more sensitive than standard radiography in the diagnosis of arthritis because radionuclide uptake precedes morphologic bone changes that are seen on radiograph. A suggestive bone scan must be interpreted in the proper clinical context and supported by microbiologic data for a definitive diagnosis of joint or bone infection.

In joints that are difficult to evaluate otherwise or that have complex anatomic structures, computed tomography (CT) and magnetic resonance imaging (MRI) can provide useful images to delineate the extent of the infection.⁶³ MRI is highly sensitive in early detection of joint fluid and is superior to CT in the delineation of soft tissue structures and soft tissue abscess. These images can show early bone erosion; reveal soft tissue extension; and facilitate arthrocentesis of joints such as shoulders, hips, acromioclavicular,⁶⁴ sternoclavicular, sacroiliac, and facet joints of the spine. MRI findings such as reactive bone marrow can suggest presence of secondary osteomyelitis, which can complicate septic arthritis. When multiple joint involvement is suspected, triple-phase bone scintigraphy is the preferred modality of investigation.

TREATMENT

Treatment of septic arthritis must begin immediately after the clinical evaluation is complete and all appropriate cultures are taken. A serious clinical suspicion of a joint infection warrants the initiation of antibiotic therapy before culture confirmation is available. Delays in treatment allow the infection to become more established in the joint and permanently damage the articular cartilage. Untreated, there is the opportunity for the joint infection to spread to other body sites via the hematogenous route and become more widespread and more difficult to cure.

The principles of treatment of an infected joint, whether natural or prosthetic, follow those of treatment of an infected body cavity in which antibiotics must be used in conjunction with adequate drainage of the infected closed space. The clinical circumstances and the preliminary laboratory data aid the selection of antibiotic agents. Host factors, any extra-articular sites of infection, and the gram-stained smear of the synovial fluid are the best early guides for the antibiotic agents with which to start. Table 109-5 lists current antibiotic agents for adults,⁵³ and Table 109-6 lists agents for children.⁶⁵

Narrow antibiotic coverage is indicated if gram-positive cocci are found in the synovial fluid, and the clinician suspects a primary source of staphylococcal infection from the skin. Appropriate monotherapy in this case may be a penicillinase-resistant penicillin or vancomycin if methicillin resistance is likely. If gram-negative bacilli are noted in the synovial fluid and the patient has a kidney infection, specific agents (e.g., ampicillin or a cephalosporin) against *E. coli* and other common urinary tract pathogens may be used. In healthy, young, sexually active individuals with community-acquired septic arthritis and a negative synovial fluid gram-stained smear, ceftriaxone is a reasonable option to cover *N. gonorrhoeae*. If synovial fluid gram stain shows

gram-positive cocci, vancomycin should be the empiric therapeutic option considering the fact that a significant proportion of community-acquired *S. aureus* infections are now methicillin resistant.⁶⁶ A reasonable initial empiric therapy to cover gonococci, *S. aureus*, and streptococci is ceftriaxone plus vancomycin pending final culture results. In elderly debilitated patients or adults with low risk for sexually transmitted disease, as well as a negative gram-stained smear of synovial fluid, broad antibiotic coverage against a wide variety of organisms including *S. aureus*, streptococci, and gram-negative bacilli should be given initially. A typical regimen includes an antistaphylococcal agent (e.g., vancomycin) plus a third-generation cephalosporin (e.g., ceftriaxone).

When the identity and the sensitivities of the organism are known, antibiotic therapy should continue with the most efficacious agent that has the best safety profile and narrowest spectrum. The parenteral route of antibiotic administration is the preferred initial treatment. Continued antibiotic therapy may be switched to oral agents if adequate blood levels can be achieved and maintained by this route. There is no evidence that the direct intra-articular instillation of drugs is necessary or preferable in septic arthritis because there is no barrier against the free diffusion of antibiotic agents from the blood to the synovial fluid. In cases in which uncertainty exists, serum and synovial fluid levels of antibiotic drugs can be measured to ensure that therapeutic levels are reached.

Although some clinicians feel that patients with native-joint septic arthritis need urgent surgical drainage, the medical literature suggests otherwise. Most individuals with septic arthritis respond adequately to appropriate antimicrobial agents after initial joint aspiration for fluid analysis. In experimental infectious arthritis cases, early antibiotic therapy was shown to reduce the loss of collagen and erosion of articular surface, which minimizes the need for open surgical drainage.⁶⁷ It is generally accepted that prompt and adequate drainage of the septic joint is essential to decrease the risks of substantial loss of articular function; however, the best approach to drain the joint remains controversial.⁶⁸

From retrospective studies, daily aspiration of an infected joint showed better functional outcome than open surgical drainage, although the former had higher overall mortality.^{69,70} An explanation for higher mortality could be the higher comorbid conditions of patients who had daily aspirations than the ones who were more fit and underwent open surgical drainage.⁶⁹ If the synovial fluid cell count and polymorphonuclear percentage decrease with successive aspiration, the antimicrobial therapy is probably effective.^{14,71} If needle aspiration is technically difficult (as in the hip or the shoulder) or does not provide thorough drainage of the joint, if the joint effusion does not resolve promptly, if sterilization of the joint fluid is delayed, if the infected joint is already damaged by pre-existing rheumatoid disease, or if infected synovial tissue or bone needs débridement, surgical drainage should be considered sooner rather than later.^{14,51,72} Arthroscopy is emerging as an alternative to arthrotomy with the advantage of reduced surgical morbidity. Wound healing is faster, and rehabilitation time is shortened.⁷³ A recent retrospective analysis from the United Kingdom suggested that most patients can be treated

Table 109-5 Antibiotic Agents Used in Adults

Synovial Fluid Gram Stain	Organism	Antibiotic	Dose
Gram-positive cocci (clusters)	<i>Staphylococcus aureus</i> (methicillin-sensitive)	Nafcillin/oxacillin	2 g IV q4h

medically (with repeated aspirations) and do not require surgical drainage (either by arthroscopy or arthrotomy).⁷⁴ Though statistically not significant, medical therapy resulted in more complete cure and less deterioration of functional status at time of discharge. Another study, which included 20 adults with native hip joint septic arthritis, concluded that symptom duration, especially if it is longer than 3 weeks before presentation, was a statistically significant predictor of the need for excision arthroplasty.⁷⁵ These results highlight the need for careful case selection for surgical intervention.

The optimal duration of antibiotic treatment has not been prospectively studied. For native joint infections caused by *N. gonorrhoeae*, a 1-week course of ceftriaxone should be adequate. For septic arthritis caused by organisms other than *N. gonorrhoeae*, therapy ranging from 2 weeks to 6 weeks is recommended depending on type, sensitivity of microorganism, and presence of osteomyelitis. If long-term antibiotics are chosen (4 to 6 weeks' duration), parenteral antibiotics may be switched to oral antibiotics after 2 weeks provided that there is clinical improvement, inflammatory markers are trending down, and oral antibiotics are available to which the microorganism is susceptible.⁵³ The duration of antibiotic administration can be 2 weeks for uncomplicated infection by susceptible microorganisms or 4 to 6 weeks for more extensive infection in an immunocompromised host. For septic arthritis caused by *H. influenzae*, streptococci, or gram-negative cocci, 2 weeks of antibiotic therapy is usually adequate. Staphylococcal septic arthritis usually requires 3 to 4 weeks of therapy, and for pneumococcal or gram-negative bacillary infections, therapy should be continued for at least 4 weeks.^{72,76}

During the first few days of management, immobilization of the infected joint by external splinting and adequate analgesic administration ensure patient comfort. Physical therapy, starting with passive then graduating to active motion, should be instituted as soon as the patient can tolerate mobilization of the inflamed joint because early active range-of-motion exercises are beneficial for ultimate functional recovery. Involving the orthopedic surgeon and the physical therapist early on in the course of treatment facilitates the best choice of drainage procedure and results in the best functional outcome.⁷⁷

PROSTHETIC JOINT INFECTIONS

Total joint replacement for advanced arthritis is one of the major advances in medicine in the 20th century and continues to improve in the 21st century. Infection of prosthetic joints is an uncommon but devastating complication of joint replacement surgery. Nearly 800,000 total knee and total hip replacements were done in the United States in 2006 (www.cdc.gov/nchs/fastats/insurg.htm), with an infection rate of 1% to 3%.⁷⁸ The infection rate is higher for knee arthroplasty (1% to 2%) compared with hip and shoulder arthroplasty (0.3% to 1.3%) and is much higher in patients undergoing reimplantation because of infection of the initial prosthesis (3% for hips and 6% for knees).^{79,80} The risk of infection is about twofold higher in patients with RA compared with patients with osteoarthritis.⁸¹

The risk of infection is related to many factors. In a retrospective study of 462 infected orthopedic implants, the

most important risks for infection included (1) a surgical site infection at a site other than the prosthesis (odds ratio [OR], 35.9), (2) a score of 2 on the National Nosocomial Infections Surveillance System surgical patient risk index (OR, 3.9), (3) the presence of a malignancy (OR, 3.1), and (4) a history of joint arthroplasty (OR, 2.0).⁸² Certain patient populations are at increased risk of infection because of comorbid conditions (e.g., diabetes mellitus and RA). Other surgical risk factors include simultaneous bilateral arthroplasty, long operative time (>2.5 hours), blood transfusion, urinary tract infection, and *Staphylococcus aureus* bacteremia.^{83,84}

Orthopedic implants adversely affect host defenses. Prosthetic devices impair opsonic activity and diminish the ability of neutrophils to kill bacteria.⁸⁵ Polymorphonuclear leukocytes release lysosomal enzymes and superoxide into the area surrounding the prosthesis, resulting in tissue damage and local devascularization.⁸⁶ Phagocytes may be focused on removal of the foreign body such that fewer cells are available to fight infection.⁸⁷ Finally, polymethyl methacrylate bone cement can inhibit neutrophil and complement functions, and the heat produced by the polymerization of polymethyl methacrylate can damage adjacent cortical bone and result in a devascularized necrotic area, which is ideal for bacterial growth. After implantation, prosthetic joints are immediately coated by host proteins including albumin, fibrinogen, and fibronectin. *S. aureus*, which possesses numerous host protein binding receptors (MSCRAMMs), is a common pathogen in infection of prosthetic joints. Patients with a prosthetic joint who develop *S. aureus* bacteremia have an approximate one in three chance of developing an infection of the implant.⁸⁸

Another phenomenon crucial to development of infection is the ability of organisms to form biofilms on the surface of the prosthetic device. A biofilm is defined as "an assemblage of microbial cells that is irreversibly associated with a surface and enclosed in a matrix of primarily polysaccharide material."⁸⁹ Biofilm formation is a natural process. Organisms grow on indwelling medical devices, potable water system pipes, and living tissues. *S. epidermidis* is particularly adept at attaching to and forming biofilms on foreign bodies such as prosthetic joints. Small numbers of these organisms from the patient's skin or mucous membranes, or from the hands of the surgeons or clinical staff, contaminate and colonize the orthopedic device at the time of implantation. Staphylococcal surface proteins, SSP-1 and SSP-2, are fimbria-like polymers that facilitate adherence of *S. epidermidis* to polystyrene.⁹⁰ *S. epidermidis* produces a polysaccharide/adhesin substance crucial to the formation of this extracellular matrix known as slime. Polysaccharide/adhesin mutants have been shown to be less virulent than the wild-type strain in a rabbit model of endocarditis.⁹¹

Prosthetic joint infections are divided into early onset (<3 months after placement), delayed (3 to 24 months postsurgery), and late onset (>24 months after placement).⁹² Early and delayed infections are usually related to surgical contamination at the time of the implantation, whereas late infections usually result from hematogenous seeding of the joint. Owing to its high virulence, *S. aureus* accounts for most early and late infections (see Table 109-1). So-called small colony variants of *S. aureus* may be responsible for persistent and recurrent infections of prosthetic implants.⁹³

These subspecies of *S. aureus* are difficult to treat because they grow slowly and are relatively resistant to cell-wall active antimicrobial agents and aminoglycosides. Delayed infections are usually caused by less virulent microorganisms such as coagulase-negative staphylococci and *P. acnes*. Because these low-virulence organisms are common skin contaminants, it is important to interpret culture results carefully.

Clinically, the most common symptom in patients with prosthetic joint infection is pain of the affected joint. Differentiating pain from mechanical loosening of the prosthesis from pain related to infection can be difficult. Typically, a patient with mechanical loosening but no infection has pain only with motion, whereas a patient with infection experiences pain at rest and with motion. Warmth at the implant site, effusion, erythema, and fever are frequently associated with early and late, but not delayed, infections. This difference in clinical presentation likely represents the virulence of the most common organisms associated with the three categories of infection. The presence of a sinus tract with purulent discharge suggests involvement of the implant and is an indication for removal of the prosthesis.

Inflammatory blood laboratory markers have variable sensitivity and specificity in the diagnosis of prosthetic joint infection. In a recent meta-analysis, elevated levels of interleukin-6 (IL-6) and CRP had a much higher sensitivity (97% and 88%, respectively) than an elevation of the WBC count or ESR (45% and 75%, respectively).⁹⁴ The specificity of an elevated level of IL-6 (91%) was the highest of these markers with elevation of WBC (87%), CRP (74%), and ESR (70%) somewhat lower. Inflammatory markers increase following arthroplasty, and the return to normal levels is quite variable. IL-6 will return to normal within a matter of a few days following surgery, whereas the CRP level may remain elevated for up to 3 weeks and the ESR for several months following arthroplasty.⁹⁴ Therefore a low or normal CRP or IL-6 level in a patient with suspected prosthetic joint infection has a good negative-predictive value. Serial plain radiographs may be helpful; the presence of subperiosteal bone growth and transcortical sinus tracts is specific for infection.⁹⁵ Bone scans using technetium 99m-labeled methylene diphosphonate are sensitive but lack specificity because the bone scan is typically positive for 6 to 12 months after the original implantation.⁹⁶ Bone scans may be a useful screening test for patients with suspected late prosthetic joint infection. CT has limitations because of the imaging artifacts caused by the metal implant. MRI can be performed only in patients with titanium or tantalum implants.

Aspiration of the joint may be helpful in differentiating infection from noninfectious causes of joint pain, particularly in patients without RA. In one study, a synovial fluid leukocyte count of greater than 1700/mm³ had a sensitivity of 94% for determining infection, whereas a differential count of greater than 65% neutrophils had a sensitivity of 97%.⁹⁷ The specificities of these two measurements were 88% and 98% in patients without underlying inflammatory diseases such as RA. Gram-stained smear of the synovial fluid has a low sensitivity (<20%) but a high specificity (>97%).⁹⁸ Cultures of drainage from a sinus tract are not helpful, unless the culture grows *S. aureus*.⁹⁹

Generally, at least three tissue specimens should be taken at the time of surgery including tissue from the joint capsule, synovial lining, bone-cement interface, and samples from purulent material or sequestrum.^{84,98} Swabs of the joint have a low sensitivity and should be avoided. Unless the patient is septic or otherwise systemically ill, antimicrobial therapy should be discontinued a minimum of 2 weeks before the revision surgery and perioperative antibiotics should not be administered until all of the tissue cultures have been obtained. Using this methodical approach, there is a direct correlation between the number of tissue specimens positive for a particular microorganism and the probability of infection. The probability of infection has been estimated to be less than 5% if all tissue specimens are negative and greater than 94% if three or more tissue specimens are positive for growth.⁹⁸ Finally, the location of the prosthesis is helpful in the interpretation of the positive culture. The isolation of *P. acnes* from a single tissue culture from a knee prosthesis is more likely to be a contaminant than if the same organism is obtained from a shoulder prosthesis.¹⁰⁰

For patients who have received recent antibiotics, there may be a role for sonication of the prosthesis at the time of explantation. A recent study determined that culturing of the explanted prosthesis that has been sonicated to remove adherent bacteria had a higher sensitivity (75%) as compared with culture of periprosthetic tissue (45%) in patients who had received antibiotics in the past 14 days.¹⁰¹

Medical therapy of patients with prosthetic joint infections is challenging. Organisms existing in biofilms are much more resistant to antimicrobial agents for several reasons. First, the drugs have difficulty penetrating the biofilm layer. The biofilm-associated organisms also grow much slower than organisms in suspension. As a result, antimicrobial agents such as vancomycin, penicillins, and cephalosporins, which act on rapidly dividing organisms, are not effective in treating device-related infections.^{102,103} Rifampin and fluoroquinolones may be more effective because they are active against organisms in the stationary phase of growth.^{103,104} Although most experts recommend rifampin in combination with another agent for the treatment of rifampin-susceptible strains of *S. aureus*, there are little clinical data to support the benefit of combination therapy versus monotherapy in the treatment of prosthetic joint infections.¹⁰⁵ The role of newer antibiotics such as linezolid, daptomycin, and tigecycline is unclear at this time.¹⁰⁶ In a rabbit experimental model of *S. aureus* osteomyelitis, the combination of tigecycline and rifampin eradicated infection in 100% of 14 rabbits.¹⁰⁷

Treatment of late prosthetic joint infections is complex. In most patients, effective therapy requires a combination of antibiotics with the removal of the orthopedic device. Failure to remove the infected prosthesis is frequently associated with an unacceptably high rate of relapse, probably related to biofilm formation on the orthopedic implant. Removal of the joint prosthesis, débridement of infected bone, and placement of a new prosthesis during the same operation has been associated with a high rate of recurrence of infection,¹⁰⁸ but studies indicate that single-stage revision or débridement with retention of the prosthesis may be effective in certain situations.¹⁰⁹ Patients whose symptoms of pain and swelling of the joint have been less than 8 days¹⁰⁹ or less than 3 weeks¹¹⁰ and who have a stable

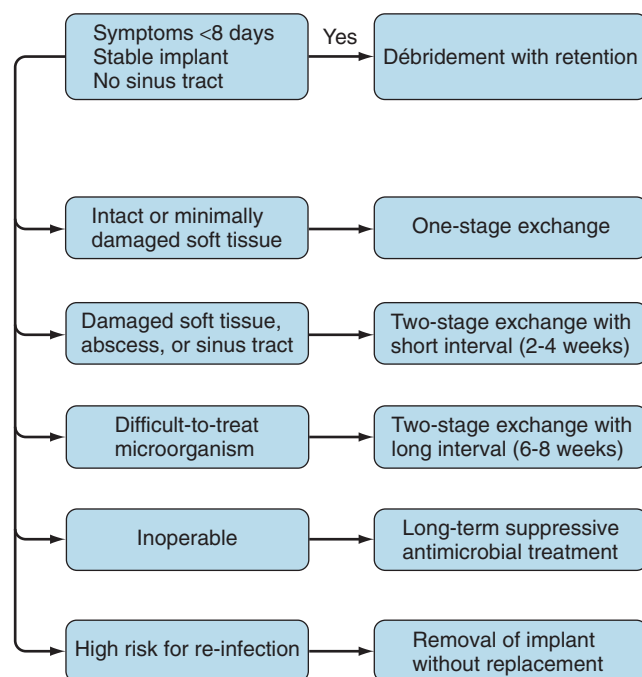

Figure 109-3 Algorithm for the management of an infected joint prosthesis. (Modified from Trampuz A, Zimmerli W: *Prosthetic joint infections: update in diagnosis and treatment*, Swiss Med Wkly 135:243–251, 2005.)

prosthesis with little soft tissue damage and no sinus tract are candidates for débridement, antibiotics, and implant retention (DAIR) if the preoperative synovial fluid cultures are negative or if the cultures grow an easily treatable organism (Figure 109-3).^{109,111} The treatment of choice for most patients is a two-stage process involving removal of the infected prosthesis and débridement of infected bone, stabilization of the joint using an antibiotic-impregnated methyl methacrylate spacer, and 6 weeks of intravenous antibiotics (first stage), followed by reimplantation of a second orthopedic implant (second stage).¹¹² Using this approach, the success rate is approximately 80% to 90%. Rarely, antibiotic treatment is continued indefinitely in a patient in whom the risk of removing the infected prosthesis is too great, the prosthesis is not loose, and the organism responsible for the infection can be reasonably suppressed by the use of an oral antibiotic agent.¹¹³

The pathogenesis of bacterial infection in prosthetic joints is complex. Anatomic, virulence, and host factors affect prognosis and approach to therapy. An understanding of these interactions may lead to novel therapeutic and preventive strategies such as vaccines against capsule antigens or surface adhesins in patients undergoing elective joint replacements.

PREVENTION OF PROSTHETIC JOINT INFECTIONS

There is consensus that preoperative evaluation of a patient for occult infection such as periodontal disease or bacteriuria is warranted, and corrective steps to eradicate any infection are essential before joint replacement. There is also consensus that perioperative antibiotic prophylaxis

significantly reduces the rate of early postoperative infection, and this practice is routine. The role of antibiotic prophylaxis to prevent late prosthetic joint infection before diagnostic or therapeutic procedures that lead to transient bacteremia, especially dental treatment, is controversial.

A position paper of the American Academy of Oral Medicine in 2010 stated that “the risk of patients’ experiencing drug reactions or drug-resistant bacterial infections and the cost of antibiotic medications alone do not justify the practice of using antibiotic prophylaxis in patients with prosthetic joints.”¹¹⁴ Many orthopedic and oral and maxillofacial surgeons have argued that there is “no scientific evidence to support the view that patients with arthroplasties, even in the high-risk groups, require antibiotic prophylaxis during dental treatment.”¹¹⁵

The incidence of late infection of a prosthetic joint as a result of procedure-related bacteremia is extremely low—10 to 100 cases per 100,000 patients with total joint replacement per year. The cost of providing antibiotic prophylaxis to all patients with prosthetic joints before all procedures that are associated with transient bacteremia is substantial. The efficacy of such antibiotic prophylaxis is unknown. Cost-effective analyses have shown mixed results.^{116,117} These discrepancies are due to the lack of reliable data and the different assumptions used in the calculations. In the patient with the greatest risk of infection, an invasive procedure that leads to bacteremia sometimes can result in an infected total joint replacement. Counseling these patients on the risks and benefits of antibiotic prophylaxis would lead to an informed decision on which the patient and the physician can agree.

As we gain experience with the use of biologic agents in the management of RA and other inflammatory arthritides, there remains the conundrum of whether the increased risk of infection from TNF inhibitor and methotrexate warrants holding them before an elective orthopedic procedure. A retrospective analysis of 10 cases of postoperative infections showed the use of a TNF inhibitor was significantly associated with the development of a serious infection (OR, 4.4).¹¹⁸ A meta-analysis of the clinical literature on TNF inhibitors through 2005 found an increased risk of serious infection.¹¹⁹ The risks and benefits must be weighed carefully, and the patients must be fully informed on how these agents should be used on a case-by-case basis.

OUTCOME

In the 21st century, patients with septic arthritis as a group are becoming older, with more risk factors for infection and more comorbidities. The number of patients with prosthetic joints is increasing as the population of older patients grows and people live longer. It is not surprising to see more cases of infection in total joint replacements. The organisms have not changed significantly, however. Staphylococci (44% to 66%) are still the dominant organisms followed by streptococci (18% to 28%) and gram-negative bacilli (9% to 19%).⁶ The emerging challenges in the treatment of septic arthritis are how to improve outcome, how to deal with resistant organisms, and how to overcome host factors that portend a poor prognosis.

The outcome of treated septic arthritis can be measured as mortality, as the functional outcome of the infected joint,

Table 109-7 Factors That Might Portend a Poor Outcome in Septic Arthritis

Older age
Pre-existing arthritis, especially rheumatoid arthritis, but also osteoarthritis and tophaceous gout
Presence of synthetic material (e.g., total joint replacement)
Delay in diagnosis or long duration of symptoms before seeking medical attention
Polyarticular infection, especially if >3 joints and small hand joints are affected
Presence of bacteremia
Infection caused by virulent or difficult-to-treat organisms (e.g., <i>Staphylococcus aureus</i> , <i>Pseudomonas aeruginosa</i> , or some gram-negative bacilli)
Patients receiving immunosuppressive therapy
Serious underlying comorbidities (e.g., liver, kidney, or heart diseases)
Peripheral leukocytosis at presentation
Worsening renal function

Data from references 36, 43, 49, 120.

or as short-term and long-term outcomes. Among the survivors, loss of articular cartilage, loss of motion, or increase in pain in the affected joint would be considered poor functional outcomes. Loss of the limb to infection and need for surgery to fuse the joint or restore function are also poor outcomes. Most studies report the outcome at the time of hospital discharge, and long-term data on adults with septic arthritis are unavailable. The rate of development of degenerative joint disease, the rate of relapse or recurrence of infection, and the rate of progression of functional impairment in the affected joint over time have not been well studied.

Many retrospective studies have characterized features that may increase the chance of a poor outcome at the time of hospital discharge (Table 109-7).^{15,47,120} One prospective community-based study of adults and children found poor joint outcome in 33% of survivors among 154 patients with bacterial arthritis and noted older age, pre-existing joint disease, and an infected joint containing synthetic material as negative prognostic factors by univariate analysis.¹²⁰ These investigators noted no association between poor outcome and young age, comorbidity, immunosuppressive medication, functional class, multiple infected joints, type of organism, or treatment delay. In a large retrospective study from the United Kingdom on the outcome of 243 patients, 11.5% died secondary to septic arthritis and additional morbidity was noted in 31.6% of patients. Multivariate analysis suggests that important predictors of death are confusion at presentation, age 65 years or older, multiple joint sepsis, and involvement of the elbow joint. Predictors of morbidity were age 65 years or older, diabetes mellitus, open surgical drainage, and gram-positive infections other than *S. aureus*.⁵²

Lyme Disease

LINDA K. BOCKENSTEDT

KEY POINTS

Lyme disease is caused by infection with tick-transmitted spirochetes of the genus *Borrelia burgdorferi sensu lato* and has a worldwide distribution.

Lyme disease has a characteristic pattern of signs and symptoms and usually begins with the expanding macular skin lesion erythema migrans.

Earlier recognition and treatment has led to a decline in the incidence of carditis, acute neurologic disease, and late disease manifestations.

Musculoskeletal manifestations occur in more than 50% of patients and at all stages of infection, but frank arthritis is a sign of late disease and is uncommon (<10% of patients).

The diagnosis of Lyme disease should be suspected when a patient who lives, works, or vacations in an endemic area presents with signs and symptoms of *B. burgdorferi* infection.

Two-tiered serologic tests (enzyme-linked immunosorbent assay and immunoblot) can be negative with early infection but become positive in most patients with infection of greater than 1 month's duration.

Most patients are cured with 2 to 4 weeks of antibiotic therapy, although the time to disease resolution may extend beyond the duration of therapy and irreversible tissue damage may occur.

Antibiotic-refractory arthritis occurs in less than 10% of patients with Lyme arthritis, responds to disease-modifying antirheumatic drugs, and typically resolves within 4 to 5 years.

Post-Lyme disease syndrome (persistent debilitating complaints of fatigue, mild cognitive dysfunction, and musculoskeletal pain) after antibiotic treatment for Lyme disease occurs in a minority of patients. *B. burgdorferi* cannot be detected in these patients, and controlled treatment trials show no benefit of prolonged antibiotic therapy over placebo.

Lyme disease is a multisystem disorder caused by the tick-borne spirochete *Borrelia burgdorferi*.¹ The disease first came to medical attention in the United States in the late 1970s with the investigation of a clustering of cases of juvenile arthritis in the region of Lyme, Connecticut.² A characteristic skin rash described as single or multiple expanding red macules often heralded the onset of arthritis.² This rash, termed *erythema migrans* (EM), had been linked in Europe to the bite of *Ixodes* ticks and the subsequent development of neurologic abnormalities.^{3,4} Further investigation revealed

that arthritis was one manifestation of a systemic disorder affecting the skin, heart, joints, and nervous system. In 1982 Burgdorfer isolated the causative agent, the spirochete *B. burgdorferi*, from *Ixodes* ticks.⁵ Demonstration that patients with Lyme disease developed antibodies to this organism and its eventual culture from skin, cerebrospinal fluid (CSF), and synovial tissue confirmed the infectious etiology of the disorder.⁶ It is now the most common vector-borne disease in the United States.¹

ECOLOGY AND EPIDEMIOLOGY OF LYME DISEASE

Lyme disease has a worldwide distribution, with most cases reported in North America, Europe, and Asia.⁷ On each of these continents, hard-shelled ticks of the *Ixodes* family are the only known vectors for the disease. Other arthropods and blood-sucking insects such as mosquitos cannot transmit the infection. The incidence of Lyme disease varies geographically and is determined by the prevalence of *B. burgdorferi*-infected ticks. In the United States, cases of Lyme disease have been reported in all 50 states and the District of Columbia, but most are clustered in the Northeast and mid-Atlantic region, upper Midwest, and northern California. In 2009, 29,959 confirmed and 8509 probable cases were reported to the Centers for Disease Control and Prevention, with 93% of confirmed cases originating from 11 states: Pennsylvania, New Jersey, New York, Massachusetts, Connecticut, Wisconsin, Maryland, Minnesota, New Hampshire, Delaware, and Maine.⁸

The spirochetes associated with Lyme disease reside within the genus *B. burgdorferi sensu lato* (sl), and the vast majority of cases are caused by *B. burgdorferi sensu stricto* (ss), *Borrelia garinii*, and *Borrelia afzelii*.⁷ All three genospecies can be found in Europe, whereas *B. burgdorferi ss* is the main species found in North America. Variation among the genospecies may account for the differences in clinical expression of Lyme disease between the two continents, with *B. garinii* associated with neurologic disease, *B. afzelii* associated with late skin involvement, and *B. burgdorferi ss* associated with arthritis.^{7,9} Because of the prominence of musculoskeletal manifestations with *B. burgdorferi ss* infection, this chapter focuses mainly on Lyme disease in North America.

TICKS AND LYME DISEASE

Lyme disease is found primarily in temperate climates where humans can have incidental exposure to questing ticks. *Ixodes* ticks have a 2-year life span in which they pass

through three developmental stages—larva, nymph, and adult—feeding only once per stage.¹⁰ *B. burgdorferi* is not passed transovarially and is maintained by passage between reservoir hosts and ticks. Small rodents are the main reservoirs for *B. burgdorferi* ss and *B. afzelii*, whereas birds are the principal haven for *B. garinii*.⁷ In the southern United States, ticks feed preferentially on lizards, which are not competent reservoirs for *B. burgdorferi*; this may explain in part the rarity of Lyme disease in this region.

Larvae acquire *B. burgdorferi* after feeding on an infected reservoir host in early spring and then molt to nymphs, which lay dormant until the following late spring and summer. The peak incidence of Lyme disease is in the summer months, when humans come in contact with questing nymphs, which have more promiscuous feeding patterns.¹⁰ Engorged nymphs molt into adult ticks, which feed almost exclusively on deer. *B. burgdorferi* does not persist in deer, which serve to maintain and propagate the tick population.

PATHOGENESIS

***Borrelia burgdorferi* Invasion of the Mammalian Host**

During tick feeding, *B. burgdorferi* migrate from the tick midgut to the salivary glands, where they are deposited with saliva into the blood meal host.^{11,12} Migration takes about 24 hours, during which time spirochetes multiply and undergo phenotypic changes that permit their survival in mammals. Spirochetes multiply first at the tick bite site in the skin, and if not eliminated by the cutaneous immune response, they can disseminate through tissues and the bloodstream to infect any organ system at least transiently. The degree to which *B. burgdorferi* cause disease in tissues depends on spirochete virulence, growth conditions that allow persistence at a particular site, and host factors that modulate the inflammatory response.

Analysis of the *B. burgdorferi* genome has revealed no known virulence factors common to other bacterial pathogens to help explain the pathogenesis of Lyme disease.^{13,14} Instead, the genome is remarkably rich in genes encoding putative lipoproteins, only a handful of which have been studied in detail. Outer surface protein (Osp) A is a midgut adhesin required for spirochete infection of ticks.¹⁵ Osp C is essential for initial infection of the mammal but is dispensable after spirochetes have disseminated and colonized other tissue.¹⁶ To do so, *B. burgdorferi* harnesses host plasmin to move through tissues^{17,18} and expresses adhesins including decorin binding proteins A and B, BBK32, and p66, which allow it to bind to extracellular matrix proteins and integrins on cells.^{19,22} Expression of VlsE, an Osp that undergoes antigenic variation, is required for infection to persist in immunocompetent hosts.^{23,24}

Pathology of Lyme Disease

Because intact spirochetes are seen only rarely in tissue specimens and the spirochete genome reveals no known toxins, the pathology of Lyme disease is believed to be due to the host inflammatory response to *B. burgdorferi* components rather than tissue destruction by the spirochete itself.

Histopathologic studies of EM lesions, cardiac tissue, synovial biopsy specimens, and limited nervous system tissue (meninges, spinal cord, and nerve roots) reveal varying degrees of monocytic and lymphoplasmacytic infiltrates, especially perivascular, that stain positively for cell surface markers for macrophages, T cells, and B cells.^{25,26} The joint effusions of patients with Lyme arthritis reveal acute inflammation with elevated leukocyte counts, whereas the synovium resembles that of rheumatoid arthritis, with chronic inflammation mediated by mononuclear cell infiltration and pseudolymphoid follicles formed by T cells, B cells, and plasma cells. In the synovium and less commonly the epineurial area, perivascular infiltrates can be associated with endarteritis obliterans.

Immune Response to *Borrelia burgdorferi*

Innate immune cells respond to *B. burgdorferi* through engagement of the Toll-like receptor (TLR) family of pattern recognition receptors, especially TLR2/TLR1 heterodimers (lipoproteins), TLR5 (flagellin), and TLR9 (spirochete DNA).²⁶ As a consequence, proinflammatory cytokines (including interleukin-1 β [IL-1 β] and tumor necrosis factor), chemokines (IL-8), nitric oxide, and prostaglandins that recruit inflammatory cells to the site of infection are produced.²⁶⁻³⁰ *B. burgdorferi* also induces matrix metalloproteinase expression in tissues through TLR-dependent and non-TLR-dependent pathways that contribute to pathology.³⁰ Other pattern recognition receptors may be engaged by *B. burgdorferi* after its ingestion by phagocytes, including the intracellular NOD2 receptors, which respond to peptidoglycan and have been shown to potentiate the inflammatory response in vitro.³¹

Humoral immunity is a key host defense against *B. burgdorferi* infection. *B. burgdorferi* lipoproteins are B cell mitogens, and antibodies that arise in the absence of T cell help are sufficient to resolve inflammation and prevent challenge infection in the mouse model of Lyme borreliosis.^{32,33} With the induction of adaptive immunity, IgG-containing immune complexes and cryoglobulins can be found in the serum of patients with Lyme disease and are concentrated in the joints of patients who develop Lyme arthritis.³⁴ B cell-recruiting chemokines such as CXCL13 and pathogen-specific antibody production can be found in the CSF of patients with neuroborreliosis^{35,36}; some of these antibodies can also bind neural antigens.³⁷⁻⁴⁰

B. burgdorferi infection primes CD4⁺ and CD8⁺ T cells, and the predominance of T helper type 1 responses correlates with more severe arthritis and neuroborreliosis.^{42,43} Th17 cells are also involved, as demonstrated by the finding that the *B. burgdorferi* neutrophil-activating protein A (NapA) can elicit IL-17 from synovial fluid T cells ex vivo.⁴⁴ There is an association between T cell and B cell responses to Osp A and the development of antibiotic-refractory Lyme arthritis.^{45,46} Although evidence has been presented to suggest an autoimmune etiology (see later section on antibiotic-refractory arthritis), the self-limited nature of Lyme arthritis also raises the possibility that the immune responses detected are appropriate and directed toward eliminating persisting antigens rather than viable organisms. Alternatively, prolonged arthritis may be due to abnormal or delayed regulation of the host immune response

when the pathogen and its inflammatory products have been eliminated. Deficiency in CD25⁺ T regulatory cells prolongs murine Lyme arthritis,⁴⁷ and synovial fluid $\gamma\delta$ T cells isolated from patients with Lyme arthritis can modulate *B. burgdorferi*-specific CD4⁺ T cell responses by inducing apoptosis in a Fas-dependent fashion.⁴⁸

Mechanisms of Spirochete Persistence

When visualized *in vivo*, *B. burgdorferi* resides primarily in the extracellular matrix in connective tissue.²⁵ Despite occasional sightings of spirochetes inside cells,⁴⁹ an intracellular phase of the *B. burgdorferi* life cycle has not been shown. *B. burgdorferi* employs immune evasion strategies of an extracellular pathogen, which are directed toward deterring phagocyte ingestion and antibody- and complement-mediated lysis.⁴ *B. burgdorferi* expresses Erp and complement regulator-acquiring surface proteins that bind host factor H to prevent complement-mediated lysis.⁵⁰⁻⁵² To impede antibody-mediated clearance, *B. burgdorferi* undergoes antigenic variation²³ and reduces expression of lipoproteins as infection progresses.⁵³ The *vlxE* gene undergoes random rearrangement of its expression locus, producing antigenically distinct variants of VlsE, a protein essential for spirochete survival *in vivo*.²³ In the chronic phase of *B. burgdorferi* infection in mice, spirochetes can be visualized in the extracellular matrix of connective tissue, especially in the skin, without an associated inflammatory response.⁵⁴

CLINICAL FEATURES OF LYME DISEASE

Lyme disease occurs in stages that reflect the immune response to the spirochete as it establishes infection in the skin and later disseminates to distant organ sites (Table 110-1). Presenting clinical manifestations depend on the stage of the illness in which patients first seek medical attention. A characteristic feature of Lyme disease is that clinical signs can resolve without specific therapy, and patients may present in later stages of the illness without exhibiting signs of early disease.

Early Localized Infection

The hallmark of Lyme disease is the skin lesion EM, which is present in about 80% of patients (Figure 110-1).⁵⁵ The lesion arises within 1 month (median, 7 to 10 days) at the tick bite site, especially in skin folds or where clothes bind in adults and around the hairline in children. EM begins as a red macule that expands at the rate of 2 to 3 cm/day, enlarging to more than 70 cm in diameter. Characteristic lesions greater than 5 cm in diameter in an appropriate clinical setting are sufficient for establishing the diagnosis of Lyme disease.⁵⁶ EM most often manifests with uniform erythema, but central clearing can occur in larger lesions, producing a classic “bull’s eye” appearance (see Figure 110-1B). Vesicular or necrotic centers are rarer (see Figure 110-1D), but even these EM lesions have relatively few symptoms other than a tingling or burning sensation. Intense pruritus or pain is unusual and should raise concern for alternative diagnoses.

EM may be accompanied by systemic flulike symptoms including low-grade fever, malaise, neck pain or stiffness,

Table 110-1 Clinical Manifestations of Lyme Disease

Early Localized Infection
Occurs 3 to 30 days after tick bite
EM in 80%-90% of patients; single lesion, occasionally associated with fever, malaise, neck pain or stiffness, arthralgias and myalgias
Systemic symptoms noted above in the absence of EM during summer months
Borrelial lymphocytoma (rare, seen primarily in Europe)
Early Disseminated Infection
Occurs weeks to months after tick bite
Profound malaise and fatigue common
Multiple EM lesions with systemic symptoms similar to early localized infection
Musculoskeletal
Migratory polyarthralgias and myalgias
Carditis (<3% of untreated patients)
Varying degrees of atrioventricular nodal block
Mild myopericarditis
Neurologic (<10% of untreated patients)
Cranial neuropathies (especially facial nerve palsy)
Lymphocytic meningitis
Radiculoneuropathies
Encephalomyelitis
Late Disease
Occurs months to years after tick bite
Arthritis (<10% of patients)
Acute monoarticular or migratory pauciarticular inflammatory arthritis, usually involving the knee
Chronic antibiotic-refractory arthritis (<10% of patients with arthritis)
Neurologic (rare)
Peripheral neuropathies
Mild encephalopathy
Encephalomyelitis (primarily seen in Europe)
Skin
Acrodermatitis chronica atrophicans (primarily seen in Europe)

EM, erythema migrans.

arthralgias, and myalgias.^{57,58} Particularly severe systemic symptoms should alert the physician to possible coinfection with another tick-borne pathogen such as *Babesia microti* or *Anaplasma phagocytophilum* (the agent of human granulocytic anaplasmosis, formerly known as *human granulocytic ehrlichiosis*). Lyme disease can also manifest with systemic symptoms alone.^{59,60} Absence of upper respiratory or gastrointestinal symptoms may help distinguish Lyme disease from common viral infections. Musculoskeletal complaints and debilitating fatigue associated with Lyme disease should be distinguished from fibromyalgia and chronic fatigue syndrome, which are typically more insidious in onset and are not associated with objective findings or laboratory abnormalities.

A newly recognized southern tick-associated rash illness (STARI) can produce a skin lesion similar to the bull’s eye form of EM.⁶¹ The rash is associated with the bite of the Lone Star tick, *Amblyomma americanum*, which is endemic to the southeastern and south-central states, but which also can be found as far north as Maine or west as central Texas and Oklahoma. Similar to EM, systemic symptoms can accompany the rash of STARI, but disease in organs other than the skin does not occur. The etiology of STARI is unknown. Although a noncultivable spirochete named *Borrelia lonestari* has been found in *A. americanum*, STARI

Figure 110-1 Erythema migrans rash of Lyme disease. **A**, Typical macular lesion on left shoulder. **B**, Bull's eye lesion on lateral thigh with central punctum. **C**, Multiple lesions on back. **D**, Lesion with vesicular center on posterior thigh. (Courtesy Juan Salazar, MD, University of Connecticut Health Center.)

patients do not develop positive Lyme serologies and the organism has not been found in skin biopsy specimens of the STARI lesions.⁶² Antibiotics resolve EM and STARI, but STARI patients recover more quickly from systemic symptoms than do patients with EM.

Early Disseminated Infection

Within weeks of the onset of infection, *B. burgdorferi* can disseminate through the skin, blood, and lymphatics to infect multiple tissues. Clinically apparent disease at this stage, however, is usually seen in the skin, heart, or nervous system. Patients with disseminated infection have debilitating fatigue and appear ill. Specific localizing signs and symptoms may fluctuate, but profound fatigue is a consistent complaint.

Skin Disease

Fifty percent of patients with untreated Lyme disease develop multiple EM lesions, a sign of disseminated infection (see Figure 110-1C).⁵⁵ Secondary lesions are typically smaller and can occur anywhere on the body, but they are most noticeable on the trunk. The lesions usually appear as flat macules and can develop partial central clearing. EM lesions may be accompanied by migratory muscle, joint, and periarticular pain that lasts hours to days, but frank arthritis is now considered a late manifestation of the disease.

Cardiac Disease

The incidence of cardiac involvement has declined to 1% in recent years, possibly owing to earlier recognition and treatment of *B. burgdorferi* infection. It most often occurs within the first 2 months of infection and manifests as varying degrees of atrioventricular block, occasionally accompanied by mild myopericarditis.⁶³ Electrophysiologic studies have mapped the conduction defect to the area above the bundle of His and involving the atrioventricular node, although multiple levels can be affected. Overt congestive heart failure is rare, and chronic cardiomyopathy, reported in Europe, has not been documented to occur in the United States.⁶⁴ Patients with Lyme carditis often have a history of EM and may have concomitant arthralgia and myalgia at the time of presentation. Absence of valvular heart disease helps distinguish Lyme carditis from acute rheumatic fever, and prominent myocardial dysfunction or pericardial involvement should suggest other infectious etiologies.

Nervous System Involvement

Acute neurologic Lyme disease occurs in less than 10% of patients and most commonly manifests as cranial nerve palsy or meningitis, although radiculopathy and encephalomyelitis are also occasionally seen.⁶⁵⁻⁶⁹ Cranial palsy occurs in 8% of cases and usually affects the seventh nerve,

resulting in unilateral or bilateral facial palsy. Even in endemic areas, however, onset of seventh nerve palsy in the nonwinter months is due to *B. burgdorferi* infection in only 25% of cases.⁷⁰ Bilateral facial palsy is seen in only a few other conditions—Guillain-Barré syndrome, human immunodeficiency virus infection, sarcoidosis, and other causes of chronic meningitis—all of which are readily distinguished from Lyme disease. Rarely, other cranial nerves (III, IV, V, VI, or VIII) may be involved. Lyme meningitis manifests with fever, headache, and stiff neck similar to viral meningitis, along with a CSF lymphocytosis and elevated protein.⁶⁸ In children, meningitis may occur with EM, cranial nerve involvement, and increased intracranial pressure (papilledema), which is rare in adults.^{68,69,71} Lyme radiculopathy typically manifests as pain, weakness, numbness, and reflex loss in a dermatomal distribution, resembling mechanical radiculopathies.⁶⁷ Lyme disease should be considered when there is no obvious precipitating factor for disk-related symptoms, and imaging studies do not delineate pathology at the appropriate root level. Untreated Lyme radiculopathy can progress to become bilateral, which helps distinguish it from mechanical disease. When truncal involvement causes unilateral chest or abdominal pain, Lyme radiculopathy is often mistaken for visceral disease or early herpes zoster before the development of vesicular lesions.

Other Organ System Involvement

A variety of other organs can exhibit pathology with disseminated *B. burgdorferi* infection including the eye (keratitis), the ear (sensorineural hearing loss), the liver (hepatitis), the spleen (necrosis), skeletal muscle (myositis), and subcutaneous tissue (panniculitis).⁷² In general, other, more classic manifestations of Lyme disease are present concurrently or have been present in the recent past to suggest the diagnosis.

Late Disease

Months after the onset of infection, untreated patients can develop late manifestations of Lyme disease, usually involving the joints (discussed separately later), nervous system, and the skin. At this stage of infection, two-tier (enzyme-linked immunosorbent assay [ELISA] and IgG immunoblot) serologic testing for *B. burgdorferi* should be positive.

Late Neurologic Disease

Late neurologic Lyme disease is now rare; patients may present with encephalomyelitis, peripheral neuropathy, or encephalopathy.^{73,74} Encephalomyelitis, seen predominantly in Europe with *B. garinii* infection, is a slowly progressive, unifocal or multifocal inflammatory disease of the central nervous system, with increased T2 signals in the white matter on magnetic resonance imaging (MRI). CSF examination often reveals a lymphocytic pleocytosis, elevated protein, and normal glucose, and serum IgG to *B. burgdorferi* and intrathecal antibody production can be found. These findings help distinguish Lyme encephalomyelitis from multiple sclerosis, which may rarely be associated with positive IgG reactivity to *B. burgdorferi* in serum and CSF samples, but there is no intrathecal antibody production.^{75,76}

Multiple sclerosis patients with positive Lyme serologies do not respond to antibiotics used for neurologic Lyme disease.

Late peripheral nervous system involvement manifests as a mild sensorimotor neuropathy in a “stocking and glove” distribution, with evidence of a mild confluent mononeuritis multiplex on electrophysiologic studies.⁷⁷ Patients may have intermittent limb paresthesias and occasionally radicular pain. The most common finding on physical examination is reduced vibratory sensation in the lower extremities. Serum IgG to *B. burgdorferi* should be present, but CSF examination is normal, consistent with disease confined to the peripheral nervous system. Patients with this form of neuropathy should be evaluated for other infectious diseases (syphilis, human immunodeficiency virus, and hepatitis C virus); metabolic disorders (especially vitamin B₁₂ deficiency, diabetes mellitus, and thyroid disease); and autoimmune diseases (antinuclear antibody [ANA] or rheumatoid factor associated).

Patients with Lyme encephalopathy complain of memory impairment and cognitive dysfunction that are best shown by formal neuropsychological testing.^{78,79} Occasionally, patients may have CSF abnormalities with elevated protein, lymphocytic pleocytosis, and intrathecal antibody to *B. burgdorferi*, but CSF examination can also be normal. Serum IgG to *B. burgdorferi* should be present, however, to consider the diagnosis. The mild cognitive dysfunction seen in patients with Lyme encephalopathy must be distinguished from neurocognitive deficits secondary to chronic stress, sleep deprivation, fibromyalgia, chronic fatigue syndrome, or aging. As for any chronic encephalopathy, toxic-metabolic causes should be excluded. Brain imaging studies are generally normal or show only nonspecific abnormalities and are not useful in establishing a diagnosis of encephalopathy associated with Lyme disease.

Late Skin Disease

The late skin lesion acrodermatitis chronica atrophicans is found mainly in Europe because of its association with *B. afzelii* infection, although any *B. burgdorferi* species can cause the lesion.⁸⁰ Acrodermatitis chronica atrophicans develops insidiously over years and is most often found on the dorsum of the hands or feet.⁸¹ It begins as a unilateral bluish red discoloration and swelling, which evolves to atrophic, cellophane-like skin with prominent appearance of the blood vessels. About 60% of patients also have a peripheral sensory neuropathy affecting the involved extremity. A prominent lymphoplasmacytic infiltrate is shown on the skin biopsy specimen. Antibiotics can lead to improvement in pain and swelling, but atrophic skin remains.

LYME ARTHRITIS AND OTHER MUSCULOSKELETAL MANIFESTATIONS OF LYME DISEASE

Musculoskeletal symptoms are common in all stages of Lyme disease and include migratory pain in joints, tendons, bursae, and muscles.⁸² Typically, musculoskeletal pain affects one or two sites at a time, lasts only hours to a few days at any one location, and is associated with significant fatigue.

The incidence of frank arthritis has declined from 50% in early studies to less than 10% in more recent years.²⁶ ELISA and IgG immunoblot for *B. burgdorferi* are positive when arthritis appears, and *B. burgdorferi* DNA can be detected by polymerase chain reaction (PCR) in synovium and synovial fluid even though cultures are usually negative. Although Lyme arthritis can resemble pauciarticular juvenile arthritis or reactive arthritis, patients generally test negative for ANA, rheumatoid factor, and anticitrullinated protein antibodies (ACPAs) and do not have an increased frequency of HLA-B27 alleles. Joint fluid analysis and synovial histopathology cannot distinguish these entities. Axial and sacroiliac joint involvement is not a feature of Lyme disease, but enthesitis can be seen. Most patients with Lyme arthritis have positive two-tier serologic tests for *B. burgdorferi* infection.

Arthritis usually begins months or years after *B. burgdorferi* infection and is predated by migratory arthralgias in half of patients.⁸² The most typical pattern is a monoarticular or oligoarticular arthritis involving one or a few large joints (fewer than five total), with the knee affected in 80% of cases. Joints are warm with large effusions, often greater than 100 mL in the knee, but comparatively little pain. Synovial fluid is inflammatory with white blood cell counts ranging from approximately 2000 to 70,000/mm³ (median \approx 24,000/mm³), with a predominance of neutrophils.⁸³ Depending on the chronicity of the arthritis, synovial biopsy specimens reveal only mononuclear cell infiltration or more advanced changes consistent with rheumatoid synovium.²⁵ Large effusions can lead to Baker's cyst formation and rupture. The temporomandibular joint is also frequently involved and in one study was the first joint to be affected in 25% of patients with arthritis.⁸² Other joints commonly affected include the shoulder, ankle, elbow, wrist, and hip. Lyme arthritis is often intermittent, with episodes lasting a few weeks to months. Recurrent episodes are notable for smaller effusions and progressive synovial hypertrophy, bony erosion, and cartilage destruction. A small percentage (<10%) of patients with intermittent arthritis settle into a pattern of chronic arthritis, generally affecting only a single joint and often the knee. Inflammation of a single joint that persists for more than 12 months would be an unusual presenting manifestation of Lyme arthritis, as is the prominent involvement of small joints.

The natural history of Lyme arthritis suggests that it is a self-limited disorder. In the late 1970s, before the use of antibiotics for Lyme disease, 21 patients who presented with EM and later developed Lyme arthritis were followed for 1 to 8 years without antimicrobial therapy.⁸² Six patients had only a single episode of arthritis, and the remaining 15 had recurrent episodes that decreased in frequency over the study period. On average, the number of patients who continued to experience episodes of arthritis decreased by 10% to 20% each year. Similar results were found in children in whom antibiotic treatment for arthritis was delayed 4 years.⁸⁴

Antibiotic-Refractory Lyme Arthritis

A few patients treated with standard antibiotic regimens for Lyme arthritis have persistent joint inflammation and proliferative synovitis that does not respond to further

antimicrobial therapy.^{26,85} The pathogenesis of "antibiotic-refractory" Lyme arthritis is unknown but may be due to persistent spirochetes or their antigens, infection-induced autoimmunity, or inadequate regulation of the inflammatory response.²⁵ Spirochete virulence may play a role as a retrospective study of archived tissue samples obtained before treatment revealed that patients who went on to develop antibiotic-refractory arthritis had a higher prevalence of infection with the more invasive RST1 *B. burgdorferi* strains.^{86,87} Although patients with antibiotic-refractory Lyme arthritis no longer have PCR evidence for spirochete DNA in tissues,⁸⁵ experiments in the mouse model of Lyme borreliosis suggest that spirochete debris, including *B. burgdorferi* DNA, can persist near cartilage and in the entheses for extended periods after infectious spirochetes have been killed with antibiotics, particularly when the initial pathogen burden was high.⁸⁸ Recently, a single nucleotide polymorphism in TLR1 (TLR1 1805 GG) that impairs the innate immune response to *B. burgdorferi* was found to be more prevalent among patients who developed antibiotic-refractory Lyme arthritis.⁸⁹ A genetic predisposition had been suggested in earlier studies that found an increased frequency of the rheumatoid arthritis-related alleles HLA-DRB1*0401, HLA-DRB1*0101, and HLA-DRB1*0404 in patients with antibiotic-refractory Lyme arthritis.⁹⁰ Because of the high prevalence of B cell and T cell responses to *B. burgdorferi* Osp A in patients with antibiotic-refractory arthritis, it had been proposed that immune responses to Osp A triggered by infection may be perpetuated by a self-antigen after the pathogen has been eliminated.^{26,90} An Osp A peptide corresponding to amino acids 163 through 175 (Osp A₁₆₃₋₁₇₅) was found to share an epitope with human leukocyte function-associated antigen 1 α , an adhesion molecule expressed on inflamed tissues.⁹¹ The leukocyte function-associated antigen 1 α peptide stimulated Osp A₁₆₃₋₁₇₅-specific T cells only weakly, however, and did not promote production of the T helper (Th)1 cytokine interferon- γ normally found in antibiotic-refractory arthritis.⁹² Antibodies to cytokeratin 10, a constituent of synovial capillaries, have been found in the blood and synovial tissue of patients with antibiotic-refractory Lyme arthritis.⁹³ These antibodies also react with Osp A and may contribute to ongoing inflammation when infection is cleared. Linked T and B cell responses to peptides of epidermal cell growth factor have been found in about 50% of patients with antibiotic-refractory Lyme arthritis, but their role in perpetuating the inflammatory response is unclear.⁹⁴ If autoimmunity is responsible for antibiotic-refractory Lyme arthritis, it must eventually succumb to immune regulation because even this form of Lyme arthritis generally resolves within 4 to 5 years.^{82,85} In this regard, the presence of a higher percentage of T regulatory cells correlates with more rapid resolution of joint inflammation after treatment for antibiotic-refractory Lyme arthritis.⁹⁵

DIAGNOSIS

The diagnosis of Lyme disease should be considered in individuals who present with an appropriate clinical history and who have a reasonable risk of exposure to *B. burgdorferi*-infected ticks (Figure 110-2).³⁶ Supporting serologic evidence is necessary to secure the diagnosis for all stages of

Figure 110-2 *Left*, Selected IgM immunoblot reactivities. *Lane 1*, Serum band locator control showing several bands including the significant 41-kD protein, 39-kD protein, and OspC (arrowheads). *Lane 2*, Serum sample from a patient with early Lyme borreliosis with erythema migrans. *Lane 3*, Serum sample from a patient with early disseminated Lyme borreliosis with multiple erythema migrans lesions. Note the larger number of bands observed in a serum sample of the patient with early disseminated Lyme borreliosis. *Right*, Selected IgG immunoblot reactivities. *Lane 1*, Serum band locator control showing several immunoreactive bands including those considered significant in the IgG blot criteria (arrowheads). *Lane 2*, Serum sample from a patient with early disseminated Lyme borreliosis with neurologic involvement. *Lane 3*, Serum sample from a patient with Lyme arthritis. *Lane 4*, Serum sample from an individual who received three doses of OspA vaccine; note the strong reactivity with OspA (31 kD) and other antigens below OspC. (From Aguero-Rosenfeld ME, Wang G, Schwartz I, et al: *Diagnosis of Lyme borreliosis*, Clin Microbiol Rev 18:484, 2005.)

infection except for early localized disease in which EM can be recognized by morphologic features alone. Routine laboratory tests are nonspecific, with some patients exhibiting mildly elevated white blood cell (neutrophil) counts, erythrocyte sedimentation rates, and liver function tests. Culture or microscopic visualization of spirochetes in clinical samples is not sensitive enough for routine use in diagnosis. Culture of a skin biopsy specimen taken from the leading margin of an EM lesion is an exception, with *B. burgdorferi* detected in more than 40% of samples, but is rarely necessary to identify EM.

Serologic Testing

Detection of antibodies to *B. burgdorferi* is the mainstay of laboratory testing for Lyme disease.³⁶ Presence of antibodies to *B. burgdorferi* at best indicates previous exposure to the organism, however, and should not be considered evidence of active infection. In nonendemic areas, about 5% of normal human serum samples yield positive results on serologic tests for Lyme disease.⁹⁶ In endemic areas,

asymptomatic IgG seroconversion to *B. burgdorferi* has been found in about 7% of subjects.⁹⁷

A two-tiered approach is recommended for detection of *B. burgdorferi*-specific antibodies.⁹⁸ An ELISA or an indirect immunofluorescence assay to detect IgM and IgG reactivity to *B. burgdorferi* should be used as an initial screening test, followed by an immunoblot (Western blot) to confirm that positive or equivocal results are due to antibodies that bind *B. burgdorferi* antigens. ELISA and immunofluorescence assays are highly sensitive tests but lack specificity because of cross-reactivity of antibodies to *B. burgdorferi* with other bacterial pathogens.³⁶ A positive or equivocal ELISA or immunofluorescence assay should be confirmed by immunoblot analysis of *B. burgdorferi* proteins (Table 110-2). Banding patterns characteristic of early infection include antibodies to the 41-kD flagellin protein and Osp C, which has a molecular weight ranging from 21 to 24 kD depending on the *B. burgdorferi* strain used (see Figure 110-2). With disseminated infection and especially with late Lyme disease, IgG reactivity to an expanding array of *B. burgdorferi* proteins can be seen (see Figure 110-2).

Some commercial laboratories have developed assays using recombinant antigens or employ criteria for the interpretation of immunoblots that have not been validated and published in peer-reviewed literature.⁹⁹ For this reason, the Centers for Disease Control and Prevention advises using only validated tests approved by the U.S. Food and Drug Administration (FDA) for serologic diagnosis of Lyme disease.

Two-tier testing for IgM and IgG should be performed for individuals with suspected Lyme disease and signs and symptoms of less than 1 month's duration, whereas only IgG results should be considered for illnesses of longer duration.⁹⁸ Positive IgM serologies alone after 1 month of illness are most often false-positive tests, which occur in the setting of other infectious diseases (especially infectious mononucleosis and other spirochetal and tick-borne infections), rheumatoid arthritis (with or without rheumatoid factor), and conditions associated with a positive ANA (systemic lupus erythematosus).¹⁰⁰ No further testing is recommended if ELISA or immunofluorescence assay results are negative. Two-tier testing has overall sensitivities of 29% to 40% in EM during the acute phase; 29% to 78% for EM in the

Table 110-2 Criteria for Western Blot Interpretation in the Serologic Confirmation of Lyme Disease

Duration of Disease	Isotype Tested	Criteria for Positive Test
First month of infection	IgM	2 of the following 3 bands are present: 23 kD (OspC), 39 kD (BmpA), and 41 kD (Fla)
After first month of infection	IgG	5 of 10 bands are present: 18 kD, 21 kD, 28 kD, 30 kD, 39 kD, 41 kD, 45 kD, 58 kD (not GroEL), 66 kD, and 93 kD

Modified from Centers for Disease Control and Prevention: Recommendations for test performance and interpretation from the Second National Conference on Serologic Diagnosis of Lyme Disease, *MMWR Morb Mortal Wkly Rep* 44:590–591, 1995.

convalescent phase; and greater than 95% in neurologic, arthritis, and other manifestations of late disease.³⁶

A peptide-based ELISA that uses a highly conserved invariant region of the VlsE protein, termed C6 (IR6), is now commercially available.^{101,102} The C6 peptide ELISA has a high degree of sensitivity and specificity in all stages of Lyme disease and may be particularly useful in early Lyme disease.¹⁰² A positive or equivocal test should be confirmed with IgM and IgG immunoblots.

After antibiotic therapy, IgM and IgG titers to *B. burgdorferi* measured by either whole cell ELISA or the C6 peptide ELISA (IgG only) generally decrease slowly but can remain positive for years.^{103,104} Repeat serologic testing is not recommended as a means for assessing response to treatment.

Detection of Antibodies to *Borrelia burgdorferi* in Cerebrospinal Fluid

In suspected cases of neuroborreliosis, intrathecal antibody production is usually assessed by measuring the ratio of IgG to *B. burgdorferi* in CSF and serum.^{36,105} Intrathecal antibody production is more commonly found in European neuroborreliosis than in North American Lyme disease, which may be due to the higher prevalence of *B. garinii* in central nervous system (CNS) infection than *B. burgdorferi* ss. Antibodies to *B. burgdorferi* may persist in CSF after treatment for Lyme disease and should not be used to assess efficacy of therapy.

Polymerase Chain Reaction

PCR has been used to detect *B. burgdorferi* DNA in a variety of clinical specimens with variable success.¹⁰⁶ The greatest utility of PCR clinically is in Lyme arthritis, in which the sensitivity of PCR for detection of *B. burgdorferi* DNA is 85%.¹⁰⁷ In contrast, the sensitivity of PCR for detecting *B. burgdorferi* DNA in CSF is low (<40%) and most often positive in patients with a CSF pleocytosis. PCR of urine specimens is not recommended because of inconsistent sensitivity and documented nonspecific amplification of non-*B. burgdorferi* DNA targets.³⁶ Although certain commercial laboratories currently offer PCR tests for *B. burgdorferi* DNA in blood or urine specimens, these have not been validated.⁹⁹ There are no FDA-approved tests for PCR-based molecular techniques for detecting *B. burgdorferi* DNA in patient specimens.

Other Tests for Lyme Disease

A urine antigen test, immunofluorescent staining for cell wall-deficient forms of *B. burgdorferi*, and lymphocyte transformation assays are offered by some commercial laboratories to aid in the diagnosis of Lyme disease. These tests have not been adequately validated for accuracy or clinical usefulness, and the Centers for Disease Control and Prevention cautions against their use.⁹⁹

Diagnostic Imaging

Imaging studies have a limited role in the evaluation of patients with Lyme disease because no feature

is sufficiently distinctive to confirm the diagnosis. Plain radiographs of arthritic joints show changes consistent with an inflammatory arthropathy including joint effusions, synovial hypertrophy, periarticular osteoporosis, cartilage loss, bony erosions, and calcified entheses.¹⁰⁸ MRI of arthritic joints can confirm the radiographic findings and reveal associated myositis and adenopathy, which may be useful in distinguishing Lyme arthritis from septic arthritis in children.¹⁰⁹

Cranial and spinal MRI findings in neuroborreliosis can reveal focal nodular lesions or patchy white matter lesions on T2-weighted images, consistent with inflammatory or demyelinating processes.^{110,111} These lesions typically resolve after treatment for Lyme disease,¹¹¹ in some cases only after several years.¹¹² In patients with post-Lyme disease syndrome, cerebral MRI and the more sensitive technique of fluid-attenuated inversion recovery are normal in about 50% of cases or show nonspecific findings of small white matter lesions.¹¹³ Positron emission tomography and single-photon emission computed tomography studies are often normal or show only nonspecific changes with subcortical and cortical hypoperfusion.^{114,115}

TREATMENT AND OUTCOME

Updated guidelines for the clinical assessment (Figure 110-3) and treatment (Table 110-3) of Lyme disease have been published.¹¹⁶ Because many of the manifestations of Lyme disease resolve without specific therapy, the goal of antibiotic treatment is to hasten resolution of signs and symptoms and to prevent later clinical manifestations. Generally, oral antibiotics are sufficient therapy for EM, disseminated EM, uncomplicated facial palsy, mild carditis (first-degree atrioventricular block), and arthritis. Disseminated infection and late manifestations of Lyme disease may require longer courses of antibiotics, and there is often a greater lag time to symptom resolution compared with early disease. Doxycycline is the antibiotic of choice in nonpregnant adults and children 8 years old and older because it is also effective against *A. phagocytophilum*, which may occur with early Lyme disease.¹¹⁶ Amoxicillin and cefuroxime axetil are acceptable alternatives for the treatment of EM, facial palsy, and other non-neurologic manifestations of Lyme disease. Macrolide antibiotics are less effective than other antimicrobials and should be used only in individuals who cannot take doxycycline, amoxicillin, or cefuroxime axetil. First-generation cephalosporins are not effective therapy for Lyme disease.

Documented nervous system involvement (other than isolated facial palsy) and symptomatic cardiac involvement are the two main indications for intravenous antibiotic therapy.¹¹⁶ Ceftriaxone administered intravenously for 2 to 4 weeks is the preferred antimicrobial, with parenteral cefotaxime or penicillin G acceptable alternatives. There is increasing evidence, however, that oral doxycycline, which is well absorbed and has a high CNS penetration, may be effective for meningitis or radiculopathy.¹¹⁷⁻¹¹⁹ Lumbar puncture is recommended in individuals with cranial nerve palsies who have symptoms of meningeal irritation because a CSF pleocytosis would be an indication to treat with intravenous therapy. Asymptomatic CSF pleocytosis can occur in the setting of facial palsy and is not an indication

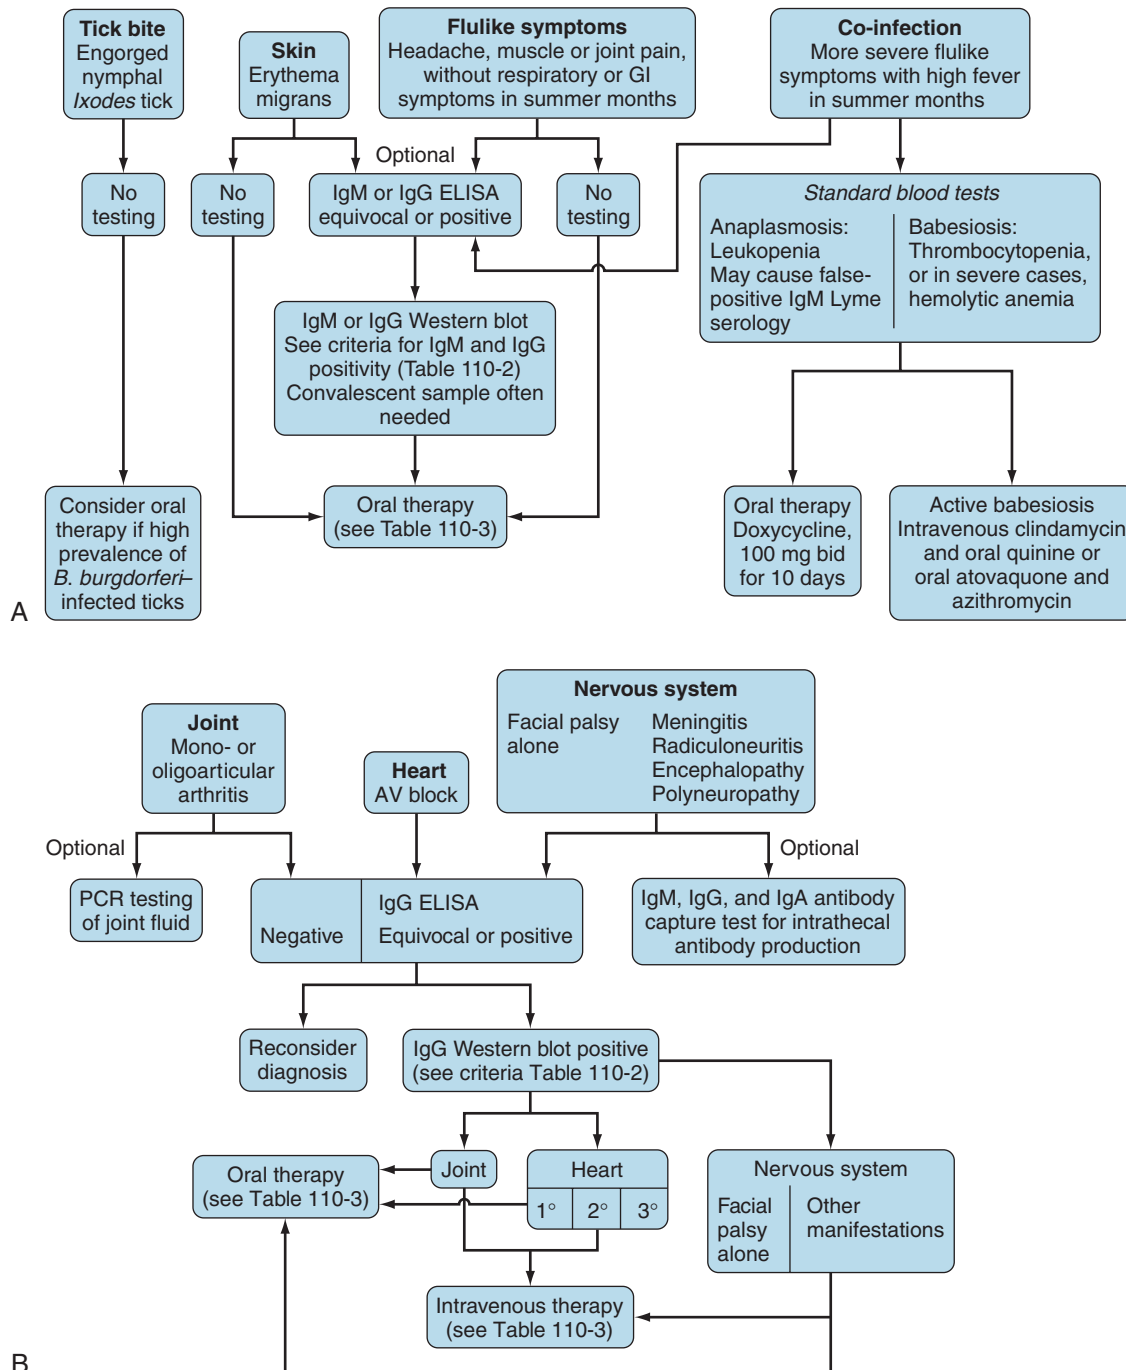

Figure 110-3 **A**, Algorithm for evaluation and management of early Lyme disease. **B**, Algorithm for evaluation and management of later organ involvement in Lyme disease. AV, atrioventricular; ELISA, enzyme-linked immunosorbent assay; GI, gastrointestinal; PCR, polymerase chain reaction. (From Steere AC, Coburn J, Glickstein L: *The emergence of Lyme disease*, J Clin Invest 113:1093–1101, 2004.)

for intravenous therapy. Repeat treatment is not recommended for chronic neurologic abnormalities, unless objective signs of relapse are present.

Patients with symptomatic cardiac involvement (chest pain, shortness of breath, syncope) or with significant conduction system disease (first-degree atrioventricular block with P-R intervals ≥ 0.3 msec, or second-degree or third-degree block) should be hospitalized for cardiac monitoring and intravenous antibiotic therapy. Consultation with a cardiologist is recommended, and placement of a temporary pacemaker may be necessary. Oral antibiotics can be

substituted for intravenous antibiotics at the time of hospital discharge to complete the course of therapy.¹¹⁶

For arthritis, a 1-month course of oral doxycycline or amoxicillin is recommended, with a repeat course of oral therapy if inflammation does not resolve within 3 months of treatment.¹¹⁶ For patients with moderate-to-severe joint swelling after a 1-month course of oral antibiotics, intravenous ceftriaxone for 2 to 4 weeks can be used¹²⁰; when inflammation is mild, an additional 1-month course of oral antibiotics can be considered, although arthritis usually resolves without additional therapy. Longer courses of

Table 110-3 Recommended Treatment of Lyme Disease*

Manifestation	Drug	Adult Dosage	Pediatric Dosage	Duration (Range)
Erythema migrans (recommended)	Doxycycline [†]	100 mg orally (PO) bid	<8 yr—not recommended ≥8 yr—4 mg/kg/day in 2 divided doses (max 100 mg/dose)	14 days (10-21 days)
	Amoxicillin	500 mg PO tid	50 mg/kg/day in 3 divided doses	14 days (14-21 days)
	Cefuroxime axetil	500 mg PO bid	30 mg/kg/day in 2 divided doses	14 days (14-21 days)
Erythema migrans (alternative) [‡]	Azithromycin	500 mg PO qd	10 mg/kg qd (max 500 mg/day)	7-10 days
	Clarithromycin	500 mg PO bid (if patient is nonpregnant)	7.5 mg/kg bid (max 500 mg/dose)	14-21 days
	Erythromycin	500 mg PO qid	12.5 mg/kg qid (max 500 mg/dose)	14-21 days
Acute neurologic disease Cranial nerve palsy [§] Meningitis or radiculopathy	Same as oral regimens for erythema migrans			14 days (14-21 days)
	Ceftriaxone	2 g IV qd	50-75 mg/kg IV qd in single dose (max 2 g/day)	14 days (10-28 days)
	(Alternative IV)	Cefotaxime	2 g IV q8h	150-200 mg/kg/day IV in 3-4 divided doses (max 6 g/day)
Cardiac disease [¶]	Penicillin G	18-24 million U/day, divided q4h	200,000-400,000 U/kg/day divided q4h (max 18-24 million U/day)	14 days (14-21 days)
				14 days (14-21 days)
Late disease				
Arthritis without neurologic involvement	Same as for erythema migrans			28 days (28 days)
Recurrent arthritis after oral regimen	Repeat oral regimen OR IV regimen as for neurologic disease			14 days (14-28 days)
Central or peripheral nervous system disease	IV regimen as for acute neurologic disease			14 days (14-28 days)

*Complete response to treatment may be delayed beyond the treatment period, regardless of the clinical manifestation, and relapse may recur. Patients with objective signs of relapse may need a second course of treatment.

[†]Tetracyclines are relatively contraindicated in pregnant or lactating women and in children younger than 8 yr of age.

[‡]Due to their lower efficacy, macrolides are reserved for patients who are unable to take or who are intolerant of tetracyclines, penicillins, and cephalosporins.

[§]Patients without clinical evidence of meningitis may be treated with an oral regimen. The recommendation is based on experience with seventh cranial nerve palsy. Whether oral therapy would be as effective for patients with other cranial neuropathies is unknown; the decision between oral and parenteral therapy should be individualized.

^{||}For nonpregnant adult patients intolerant of β -lactam agents, doxycycline 200-400 mg/day orally (or IV if unable to take oral medications) in 2 divided doses may be adequate. For children 8 yr of age and older, the dosage of doxycycline for this indication is 4-8 mg/kg/day in two divided doses (maximum daily dosage of 200-400 mg).

[¶]A parenteral antibiotic regimen is recommended at the start of therapy for patients who have been hospitalized for cardiac monitoring; an oral regimen may be substituted to complete a course of therapy or to treat outpatients. A temporary pacemaker may be required for patients with advanced heart block.

antibiotics provide no additional benefit when PCR for *B. burgdorferi* in joint fluid is negative.⁸⁵ In this situation, nonsteroidal anti-inflammatory drugs and hydroxychloroquine are recommended for treatment of antibiotic-refractory Lyme arthritis. In rare patients who fail to respond to this approach, other disease-modifying antirheumatic drugs such as methotrexate and tumor necrosis factor inhibitors have been used anecdotally with success. Arthroscopic synovectomy is curative in most patients who fail to respond to medical management.¹²¹ Intra-articular corticosteroids may be associated with a higher rate of antibiotic unresponsiveness and are rarely used.⁸⁵

Pregnancy and Lyme Disease

Pregnant and lactating women with Lyme disease can be treated with the same antibiotic regimens recommended for

nonpregnant patients except that doxycycline should be avoided.¹¹⁶ Maternal-fetal transmission of *B. burgdorferi* does occur,¹²² but in contrast to syphilis in pregnancy, there is no evidence that the organism causes a congenital syndrome.^{123,124} Pregnant patients should be reassured that with recommended therapy for Lyme disease, *B. burgdorferi* infection in the mother should not cause harm to the fetus.¹²⁴

Expected Outcomes

Most patients treated for Lyme disease with recommended courses of antibiotics experience resolution of all signs and symptoms of the disorder.^{68,125,126} About 15% of patients treated for Lyme disease may experience a Jarisch-Herxheimer reaction, a self-limited worsening of symptoms within 24 to 48 hours of initiation of antibiotic therapy.⁴ Within the first week of treatment, patients may rarely show

evolution of disease such as the development of new EM lesions or facial nerve palsy, but these signs should improve as therapy progresses. Most patients with Lyme arthritis experience resolution of joint inflammation after a 1-month course of oral antibiotics, and less than 10% of patients progress to antibiotic-refractory arthritis, which nevertheless resolves within 4 years.⁸⁵

Subjective complaints of fatigue and musculoskeletal pain may persist for months after treatment for Lyme disease.¹²⁷ When patients complain of persistent pain and fatigue, evaluation for co-infection with *B. microti* or *A. phagocytophilum* should be performed.¹²⁸ Patients with coinfection tend to be more symptomatic at presentation and can have a delayed resolution of symptoms compared with patients with Lyme disease alone. Objective, nonprogressive signs such as mild facial weakness after facial palsy are likely due to irreversible tissue damage, and further antibiotic therapy does not seem to be beneficial.¹²⁹⁻¹³²

Chronic Lyme Disease and Post-Lyme Disease Syndrome

There is a great deal of controversy over the potential for Lyme disease to cause life-altering chronic morbidity in patients. It is unusual to have objective signs after recommended antibiotic regimens for Lyme disease diagnosed according to the guidelines discussed earlier, and when such signs (e.g., Lyme arthritis) are present, further antibiotic therapy does not alter outcome.⁸⁵ Even when objective signs are present, they are usually nonprogressive (e.g., residual facial weakness after facial palsy) or resolve over time (as is the case for Lyme arthritis). Use of the term *chronic Lyme disease*, which implies ongoing infection, for nonprogressive signs and symptoms after Lyme disease is not valid.

A few patients treated for Lyme disease may have fatigue, musculoskeletal pain, and complaints of memory impairment despite conventional or prolonged courses of antibiotic therapy, a condition referred to as *post-Lyme disease syndrome*.^{129,133} In several controlled, population-based cohort studies that used validated standardized measures of outcomes (e.g., SF-36), patients with Lyme disease had more joint pain, symptoms of memory impairment, and worse functional status because of pain compared with controls.^{126,134,135} These complaints could not be documented by abnormalities on physical examination or by neurocognitive testing, however, and a follow-up study showed that quality-of-life measures improved with time.¹³⁶ Psychological factors and the presence of psychiatric comorbidity in patients with Lyme disease correlate with poor functional outcomes after treatment.¹³⁷ More recently, a European study demonstrated that the frequency of nonspecific symptoms at 6 and 12 months after treatment for early Lyme disease was no greater than that of the control group, which included family members without a history of Lyme disease.¹³⁸ Children are less likely than adults to have persistent complaints after treatment for Lyme disease.¹³⁵

Two randomized, double-blind, placebo-controlled trials of antibiotic therapy were conducted on seropositive and seronegative patients with chronic symptoms (>6 months) after treatment for Lyme disease.¹³⁰ Patients were randomly assigned to receive either intravenous ceftriaxone for 1 month followed by 2 months of oral doxycycline or matched

intravenous and oral placebos. An interim analysis of the first 129 subjects enrolled (78 seropositive, 51 seronegative) resulted in termination of the study because no differences in outcome between groups receiving antibiotics or placebo were found, and evidence of ongoing infection could not be documented. Another trial of antibiotics for post-treatment Lyme disease symptoms found that fatigue, as assessed by the Fatigue Severity Scale–11, improved in the group receiving intravenous ceftriaxone, but cognitive dysfunction did not.¹³¹ Individuals who had positive IgG immunoblots for Lyme disease and who had not received prior treatment with intravenous antibiotics were more likely to have improvement in fatigue. Subsequently, a randomized, placebo-controlled trial of a 10-week course of intravenous ceftriaxone for memory impairment after treatment for Lyme disease did not show sustained improvement in cognitive function.¹³² An open pilot study provided evidence that gabapentin may be effective in the treatment of chronic pain syndromes after Lyme disease.¹³⁹

A growing number of patients with similar subjective complaints are being treated for months or years with antibiotics for presumed *B. burgdorferi* infection.¹⁴⁰⁻¹⁴⁴ These patients are diagnosed with *chronic Lyme disease* even though they often have no serologic evidence of *B. burgdorferi* exposure or are considered as testing positive on the basis of IgM reactivity on immunoblot despite years of not feeling well. They typically experience only partial resolution of their symptoms with antibiotics. Occasionally, patients may have other conditions such as rheumatoid arthritis or fibromyalgia, for which therapy has been delayed because of a misdiagnosis of Lyme disease.¹⁴⁰ Musculoskeletal pain is common in the general population; 20% to 30% of adults complain of chronic fatigue.¹⁴⁵ In the absence of a clinical history with objective manifestations of Lyme disease or positive two-tiered serologic tests, definitive attribution of symptoms to *B. burgdorferi* infection cannot be made. Caution should be exercised when attributing the response of symptoms to the antimicrobial effects of antibiotics. Ceftriaxone and other β -lactam antibiotics can modulate neurotransmitter activity,¹⁴⁶ and tetracyclines inhibit matrix metalloproteinases.^{147,148} Prolonged antibiotic use is not without risk. Minor side effects are common, and serious adverse events such as biliary complications from ceftriaxone therapy or indwelling catheter-related infections occur at high enough rates to warrant only judicious use of antibiotics.^{130,132,142}

PREVENTION

The most effective way to prevent Lyme disease is to reduce exposure risk to *B. burgdorferi*-infected ticks through personal protective measures and environmental controls.¹⁴⁹ These measures include avoidance of tick habitats such as wooded areas, stone fences, woodpiles, and tall grass; wearing protective clothing; and performing daily surveillance and prompt removal of ticks (within 24 hours of feeding). Other effective measures include use of DEET-containing insecticide sprays, yearly application of acaricides to property to kill ticks, construction of four-poster bait stations that apply acaricides onto deer as they feed, and tall fences to prevent deer from incidentally transporting ticks to an area.

A single 200-mg dose of doxycycline (or 4 mg/kg up to 200 mg for children 8 years old and older) has been shown to reduce the incidence of Lyme disease after a recognized tick bite¹⁵⁰ but is not routinely recommended because of the low rate of infection.¹¹⁶ An FDA-approved recombinant Osp A-based vaccine to prevent Lyme disease was withdrawn because of low market demand and concern for potential vaccine-related side effects.^{151,152}

SUMMARY

Lyme disease is a localized or systemic infection that usually manifests with skin and musculoskeletal signs and symptoms, but it can involve other organ systems, especially the heart and nervous system. The diagnosis should be based on objective clinical findings consistent with Lyme disease and supporting serologic tests. Most patients are cured with 2 to 4 weeks of antibiotic therapy, although the time to disease resolution may be prolonged, especially for individuals in whom therapy was delayed; irreversible tissue damage may occur. A poor response to antibiotic therapy should raise concern for alternative diagnoses or co-infection with other tick-borne pathogens. Arthritis becomes refractory to antibiotics in less than 10% of patients with Lyme disease. Treatment with nonsteroidal anti-inflammatory drugs and hydroxychloroquine usually resolves arthritis within 4 to 5 years. Some patients treated for Lyme disease develop a post-Lyme disease syndrome of fatigue, headaches, mild memory impairment, and musculoskeletal pain. Ongoing infection cannot be shown, and controlled treatment trials show no benefit of prolonged antibiotic therapy over placebo. Referral to an academic medical center with experience in the diagnosis and treatment of Lyme disease should be considered when patients do not respond as expected to therapy.

Mycobacterial Infections of Bones and Joints

ERIC M. RUDERMAN • JOHN P. FLAHERTY

KEY POINTS

Global rates of tuberculosis disease have increased due to the expanding human immunodeficiency virus pandemic and the growing problem of antituberculous drug resistance; rheumatologists have seen an increase in tuberculosis disease in response to the expanded use of anti-tumor necrosis factor (TNF) agents.

Musculoskeletal tuberculosis typically presents as a chronic localized infection, most commonly involving the spine, less often the hip or knee.

Diagnosis may be very difficult and often requires biopsy for histopathology and culture of the bone or synovium; rapid diagnostic test techniques have not yet proven reliable in bone and joint specimens.

The tuberculin skin test can be helpful in identifying latent tuberculosis before treatment with anti-TNF agents, but it is limited by false-positive and false-negative results; the availability of interferon- γ release assays, when available, may be a useful alternative screening procedure.

Treatment requires multiple agents selected on the basis of susceptibility testing for 6 to 9 months and has been complicated by the increasing incidence of drug resistance.

Nontuberculous mycobacteria are becoming important pathogens to recognize in the face of biologic therapy for rheumatic diseases.

Recognition of tuberculosis (TB) and other mycobacterial infections of the musculoskeletal system has become a major challenge for rheumatologists in the United States and in other developed countries. Before 1999, most rheumatologists could easily go an entire year without seeing a single case of mycobacterial infection. Such cases were rare even at academic centers, where they would likely be presented as unusual teaching cases at clinical conferences.

However, 1999 introduced the routine clinical use of anti-tumor necrosis factor (TNF) therapy in the United States, and with it came an unexpected increase in TB cases seen by rheumatologists. Fortunately, the initiation of routine screening with tuberculin skin tests (TSTs) and other methods has led to a sharp decline in the number of new cases, particularly those associated with reactivation of latent infection. However, the risk of primary infection with new exposure mandates continued vigilance in these patients and potentially in patients on other biologic therapies. Moreover, for non-TB mycobacterial infections, no screening tests are available, making vigilance on immunosuppressive therapy even more important.

Another major force driving the increase in mycobacterial infection is the human immunodeficiency virus (HIV)

epidemic that continues to be a worldwide problem. By 1991, 21% of extrapulmonary TB cases in the United States were associated with acquired immunodeficiency syndrome (AIDS). In developing countries, the HIV pandemic has led to marked increases in osteoarticular TB co-infection.¹ These cases are distinguished by disseminated multifocal disease suggestive of hematogenous spread, rapid progression, and more common coexistence with pulmonary infection.^{2,3} HIV testing should be a routine part of the workup of any patient presenting with a musculoskeletal infection secondary to *Mycobacterium tuberculosis*. Since the introduction of effective antiretroviral therapy, the incidence of TB and nontuberculous mycobacterial infection in patients co-infected with HIV has sharply declined in the United States.

Although TB is uncommon among the non-HIV-infected population in the developed world (in the United States, TB is steadily declining among the general population), it remains a major problem in developing countries. There, TB continues to ravage the population, with 9 million new cases of active disease and 1.6 million deaths each year.⁴ Worldwide, it is the number two infectious disease killer after HIV/AIDS. Someone in the world is newly infected with TB bacilli every second. About one-third of the world's population is infected with TB, providing a reservoir that will continue to complicate its global control.⁵ More alarming is the emergence of extensively drug-resistant TB (XDR-TB).⁶ These strains fail to respond to all first-line and most second-line TB agents. An outbreak of XDR-TB in South Africa was associated with a mortality rate of 100%, with a median survival of only 16 days after diagnosis. Globalization of the world economy is encouraging increased contact between populations of the developed and developing worlds. Recent immigrants to the United States from endemic areas constitute an expanding reservoir of patients with latent TB.

The challenge of diagnosing musculoskeletal mycobacterial infection reaches beyond the rarity of the disease. Such infections are often indolent and may lack the pain, fevers, chills, and other prominent symptoms that typically accompany bacterial infections of the musculoskeletal system. In addition, unless the diagnosis of TB is a consideration from the outset, routine culture techniques will not isolate the organism. Delay in the diagnosis of mycobacterial infection of the musculoskeletal system is common and will continue without a heightened index of suspicion for these types of infections.

For all these reasons, 21st century rheumatologists need to be well informed about a group of diseases with which they may have had little or no experience during their formal medical training.

CLINICAL SCENARIOS

To appreciate the entire spectrum of clinical problems that a rheumatologist may encounter in dealing with mycobacterial infection, it is useful to think in terms of several distinct categories. Franco-Paredes⁷ and colleagues provided a clinically useful division of mycobacterial infections into four major categories. The following sections reflect that division.

Direct Involvement of the Musculoskeletal System

Musculoskeletal infections caused by mycobacteria typically present as chronic, indolent, localized involvement of the bones, spine, peripheral joints, or soft tissues that produces a focus of nonspecific pain and, less often, swelling. In infections initiated by direct tissue inoculation, the traumatic event is often trivial or remote in time from the onset of clinical disease. Diagnosis may be delayed for months to years, in part because of minimal early symptoms and attribution of those symptoms to a noninfectious disorder until disease progression and disability prompt a more aggressive diagnostic investigation.

Constitutional symptoms are typically subtle or absent, and laboratory indicators of inflammation are often normal. Synovial effusion is frequently minimal, and the fluid, if it is attainable, shows nonspecific inflammation. Radiographic abnormalities may be delayed, although newer imaging techniques have allowed the earlier detection of abnormalities and the distinction of TB from other infections and neoplasm.^{8,9} Characteristic pulmonary or extrapulmonary findings are not always present; for example, less than 50% of osteoarticular TB presents with evidence of active or past pulmonary disease. Tuberculin skin tests (TSTs) and interferon- γ release assay (IGRA) testing may provide useful clues to the cause, but results are not invariably positive, especially in debilitated or immunosuppressed patients. Correct diagnosis is highly dependent, in most cases, on demonstration of the infectious agent by microscopic examination and culture of affected tissue.

In HIV-infected patients, mycobacterial infections are often diagnosed before patients' HIV-positive status is known, sometimes leading to its recognition.¹⁰ Atypical pulmonary TB and extrapulmonary (often multifocal) infection are common; extrapulmonary infection occurs in 60% to 70% of such cases, compared with 16% of all TB patients.

The clinical patterns of musculoskeletal TB include spondylitis, osteomyelitis, peripheral joint infection, and soft tissue abscess. In a series of 230 consecutive cases of TB from the preantibiotic era, 5.2% had skeletal involvement; the spine was affected in 60% of these cases.¹¹ TB of the bones and joints is spread hematogenously. The sites most commonly affected are the spine and hips, followed by the knees and wrists; other joint involvement is rare. Constitutional symptoms are unusual in musculoskeletal TB and, when present, suggest TB in other organs. Vertebral collapse due to spinal TB may initially be attributed to the more common osteoporosis-caused spinal compression fracture. TB only rarely involves skeletal muscle but must be considered in the differential diagnosis of an enlarging muscle

lesion.¹²⁻¹⁶ Isolated cases involving tendons, trochanteric bursae, and fasciae latae illustrate the variety of possibilities.¹⁷⁻¹⁹ Biopsy and culture are required for diagnosis. Imaging studies do not reliably distinguish TB from neoplasm.

In nonendemic areas, skeletal TB usually occurs in elderly, debilitated patients, most often in the form of solitary osteolytic lesions in the axial skeleton. The development of skeletal disease is often remote from the initial infection, which strongly implies reactivation of previous subclinical disease. Patients may have false-negative TSTs for several reasons, including long-term corticosteroid use or coexisting debilitating disease, such as rheumatoid arthritis or chronic renal failure, which compromises resistance and produces anergy (Table 111-1).^{20,21} Spinal disease in children in nonendemic regions has largely been eliminated by effective medical therapy of pulmonary infection.

In contrast, in endemic areas with high infectivity rates, those infected are more commonly children and young to middle-aged adults. These individuals have a higher incidence of multifocal skeletal involvement in the ribs, pelvis, vertebral appendages, cervical spine, feet, and long bone diaphyses, and they show positive TST reactivity.²² Bone seeding occurs through hematogenous spread, sometimes secondarily from another extrapulmonary site. When pulmonary findings are present, a miliary pattern is typical. Spread to bone may also occur from infected nodes, by direct extension or through draining lymph channels.²³

Spondylitis

The spine is the dominant site of involvement in skeletal TB, accounting for 50% to 60% of cases.²⁴ Between 48% and 67% of lesions occur in the lower thoracic and thoracolumbar spine in HIV-negative patients, whereas the lumbar spine is most commonly involved in HIV-positive patients.⁵ Infection usually begins in the anterior subchondral bone of a single vertebra adjacent to the intervertebral disk (Figures 111-1 and 111-2). Progression to bone takes 2 to 5 months and begins with extension from cancellous to cortical bone, and then across the disk space to adjacent vertebrae (Figure 111-3). Bone destruction may lead to vertebral collapse, which typically occurs anteriorly, resulting in gibbus deformity. Isolated neural arch involvement and intraspinal abscess may also occur.

Paravertebral abscess begins with extension of infection under the anterior longitudinal ligament. In the thoracic spine, it may extend into the pleural space and the lung parenchyma. In the cervical region, it may present in the posterior cervical triangle or the retropharyngeal space. In the lumbar spine, a cold abscess characteristically produces lateral displacement of the psoas muscle and may dissect

Figure 111-1 Tuberculous spondylitis: sites of involvement. Tuberculous lesions can localize in the vertebral body (1) or, more rarely, in posterior osseous or ligamentous structures (2). Extension to the intervertebral disk (3) or prevertebral tissues (4) is not infrequent; subligamentous spread (5) can lead to erosion of the anterior vertebral surface. (From Resnick D: *Diagnosis of bone and joint disorders*, ed 3, Philadelphia, 1995, WB Saunders, p 2464.)

along its length to present as a mass in the inguinal triangle, gluteal muscle, or upper thigh. In isolated cases, a cold abscess occurs without apparent bone involvement.

A particular variant of this presentation is subligamentous TB, in which infection spreads up and down the spine beneath the longitudinal ligament, producing scalloping of multiple anterior vertebral bodies without disk involvement. This pattern is more common in the cervical spine.²⁵

The clinical presentation of spinal TB usually consists of localized pain, which may be accompanied by low-grade fever, weight loss, chills, and nonspecific constitutional

symptoms. Paraparesis and paraplegia have been reported in 1% to 27% of patients in various series. In comparison with pyogenic vertebral osteomyelitis, spinal TB more often presents with a prolonged clinical course, thoracic segment involvement, absence of fever, spinal deformity, neurologic deficit, and paravertebral or epidural masses.²⁵ On occasion, tuberculous spondylitis may present with chronic inflammatory-type back pain more typical of a spondyloarthropathy.²⁶

Mycobacterial colony counts in bone biopsy specimens are relatively low. Only 40% of smears and cultures from psoas abscesses are positive. Among patients meeting strict clinical and radiographic criteria in one series, between 73% and 82% had compatible histologic features on biopsy; of these, 80% to 95% had positive cultures.²³ The differential diagnosis, which is extensive, includes pyogenic and fungal osteomyelitis, primary and metastatic tumors, sarcoidosis, multiple myeloma, and eosinophilic granuloma.

Cervical spine involvement is relatively rare, accounting for only 0.4% to 1.2% of cases of extrapulmonary TB in the United States.²⁷ The most common presenting symptoms are neck pain and stiffness, although hoarseness, dysphagia, torticollis, fever, anorexia, and neurologic disorders may also occur. Spinal involvement can progress to myelopathy because of delays in diagnosis. Radiographs may show characteristic osteolysis of the anterior vertebral body with sparing of the posterior portion, gibbus deformity, disk involvement, and a partially calcified paraspinal mass. Computed tomography (CT) or magnetic resonance imaging (MRI) is useful for assessing compromise of the spinal canal. Retropharyngeal infection may extend into the craniocervical junction and, if not promptly recognized, may cause atlantoaxial dislocation and neurologic complications.^{28,29}

The sacroiliac joint is involved in up to 10% of cases of skeletal TB, often without other evidence of disease.³⁰ Infection, TB in particular, should be considered in all cases of unilateral sacroiliitis, particularly when other features of a spondyloarthropathy are absent. Emigration from an endemic area and a past history of TB increase the likeli-

Figure 111-2 Tuberculous spondylitis with discovertebral lesion. **A**, The initial radiograph reveals subchondral destruction of two vertebral bodies, with mild surrounding eburnation and loss of intervertebral disk height. The appearance is identical to that in pyogenic spondylitis. **B**, Several months later, an osseous response is evident. Note the increased sclerosis. Osteophytosis and improved definition of the osseous margins can be seen. (From Resnick D: *Diagnosis of bone and joint disorders*, ed 3, Philadelphia, 1995, WB Saunders, p 2465.)

Figure 111-3 Tuberculous spondylitis with spinal cord compression. Magnetic resonance image of the lumbar spine shows destruction of contiguous vertebral bodies and an inflammatory mass pressing on the spinal cord. This patient was successfully treated with medical therapy alone.

hood of this cause. Buttock pain on the involved side is the presenting symptom and is often accompanied by proximal leg or radicular pain. Examination reveals sacroiliac tenderness to palpation and stress maneuvers. Sacroiliac films show joint widening and erosion. An elevated erythrocyte sedimentation rate (ESR) and anemia are common, and a positive tuberculin reaction is typical. Biopsy of the sacroiliac joint shows granulomatous histologic features or nonspecific inflammation and a positive culture in most cases.

Atypical spinal lesions, which occur in about 10% of cases, may lead to delayed diagnosis and treatment. Atypical radiographic presentations in a single vertebra include concentric collapse, sclerotic foci, and selective involvement of the vertebral arches and costovertebral joints. Multiple vertebrae may be involved in continuity or as skipped lesions. Atypical clinical presentations may suggest a herniated intervertebral disk, failed back syndrome, spinal tumor, or a meningeal granuloma.^{24,31}

Tuberculous Osteomyelitis

Bone lesions begin with hematogenous implantation of organisms in the medullary area. Metaphyseal involvement is most common, and lesions may spread through the growth plate to involve the adjacent joint, usually late in the disease course. Lesions are typically destructive. Lytic lesions in unusual areas, such as the pubic symphysis, sacroiliac joint, and elbow, can be misdiagnosed as malignancy.³² Osteomyelitis may develop in a bone or a joint that has been previously exposed to trauma.

Tuberculous osteomyelitis occurs in both children and adults.³³ Although any bone can be involved, the femur and the tibia are most commonly affected. Dactylitis may also occur in children. In one large series from an endemic area,

such cases represented 19% of bone and joint TB and 15% of cases of osteomyelitis of hematogenous origin.³⁴ Bone pain was the most common presentation; a draining sinus, abscess formation, and local swelling and tenderness were also common. The average delay before diagnosis was 28 months.

Multifocal osteoarticular TB is a less common variant of the disease,^{34,35} but TB should be considered in all patients from endemic areas who present with multiple destructive skeletal lesions.

For a definitive diagnosis of osteoarticular TB, a biopsy specimen of an affected site must be obtained.¹⁸ Soft tissue lesions characteristically demonstrate rim enhancement on CT examination. CT may also facilitate percutaneous needle biopsy or abscess drainage.³⁶ Histologic examination generally reveals granulomatous inflammation. In one series of 121 cases, biopsy showed a positive culture in 33%, granulomatous histologic features in 46%, and both in 21%.³⁷ Radiographic findings include cavity formation with a thin adjacent layer of sclerosis in about 50% of cases, sometimes containing a sequestrum. The true extent of bone involvement may be difficult to detect because of clinically silent lesions. Bone imaging with technetium 99, although more sensitive than conventional radiographs, may provide false-negative information in early, indolent, or highly destructive disease. Tuberculin test reactions are positive in more than 80% of cases.³⁸

Treatment with chemotherapy is generally effective. In a minority of cases, surgical débridement is required for healing. Initiation of therapy on the basis of histologic findings is appropriate pending culture results. Sinus cultures are commonly positive for pyogenic bacteria both before and after antituberculous therapy, but these are presumed to be contaminants. Healing is associated with sclerosis at the margin of lesions. Misdiagnosis of the condition as pyogenic osteomyelitis may lead to unnecessary surgery or to delayed antituberculous treatment, resulting in extension of infection into the joint and chronic disability.

Septic Arthritis

Tuberculous joint involvement is second in frequency to vertebral infection.²⁴ The typical pattern is a monoarticular arthritis involving the large joints, most commonly the hip and knee (Figures 111-4 and 111-5).^{39,40} Other joints less commonly involved include the sacroiliac, shoulder, elbow, ankle, carpal, and tarsal joints. Infection begins in the synovium, with slower progression of destructive changes than in pyogenic septic arthritis. Prosthetic joint infection with *M. tuberculosis* has been reported and usually is caused by local reactivation of latent disease.⁴¹

The diagnosis of tuberculous arthritis is often missed. A consecutive series spanning the years 1970 to 1984 emphasized typical features.⁴² Of 23 cases of musculoskeletal TB, 9 involved the spine, 1 the hip, and the remaining 13 the peripheral joints. Most patients were men older than 50 years. The history of TB or exposure was generally forgotten. In all cases, presenting symptoms included joint pain and swelling. Four patients had evidence of active pulmonary TB, and in two patients with sterile pyuria, *M. tuberculosis* grew from the urine. Only 5 of 10 patients tested had a positive TST. Radiographs showed changes of erosive

Figure 111-4 Tuberculous arthritis of the knee. On conventional computed tomography, typical marginal and central osseous erosions (arrows) accompany tuberculous arthritis. Osteoporosis is not prominent. (From Resnick D: *Diagnosis of bone and joint disorders*, ed 3, Philadelphia, 1995, WB Saunders, p 2480.)

arthritis in 7 and no changes in 4 of 11 joints studied. The median delay in diagnosis was 8 months.

Arriving at a correct diagnosis requires vigorous pursuit and usually a synovial biopsy and culture. Initial studies are often misleading and may contribute to delayed diagnosis or misdiagnosis. Synovial fluid findings are variable and do not distinguish this arthropathy from other inflammatory or

septic arthritides.⁴³ Cell counts more often suggest bland inflammatory, rather than septic, arthritis and may contain a preponderance of neutrophils. The diagnosis may be facilitated if the organism is observed on an acid-fast smear of synovial fluid, but only 10% to 20% of reported cases are positive. In contrast, synovial fluid cultures are frequently positive. Radiographic changes are similar to those seen in other septic arthritides, beginning with juxta-articular bone demineralization and progressing to marginal bone erosion and articular cartilage destruction (see Figure 111-4).

With the open biopsy technique, granulomatous histologic features and positive cultures are present in more than 90% of cases.⁴³ No data are available for direct amplification tests in mycobacterial arthritis, but their use can be considered in suspected cases to arrive at an earlier diagnosis. The histologic examination alone may be confusing, because granulomatous synovitis can also be found in nontuberculous mycobacterial infection, sarcoidosis, erythema nodosum, brucellosis, Crohn's disease, and foreign body reaction. As noted, synovial acid-fast smear is of limited value. Tuberculous arthritis is also reported in children, sometimes early in the disease course; synovial biopsy and culture are recommended in children with monoarthritis and a positive tuberculin reaction.⁴⁴

TB must be considered among the possible causes of septic arthritis in patients with pre-existing rheumatoid arthritis, although it is not widely seen in developed countries.^{45,46} Conversely, rheumatoid factor may be present in TB, leading to diagnostic confusion in the presence of chronic monoarthritis.⁴⁵

Emergence of Tuberculosis during Treatment of Rheumatic Disease

Many patients with systemic rheumatic disease have dysregulated immune systems that are treated with immunosuppressive drugs. Such an impaired immune response may permit the reactivation of latent TB. TNF plays a key role in granuloma formation and stabilization, which promotes the containment of *M. tuberculosis*. The rate of TB among patients with rheumatoid arthritis before the widespread use of anti-TNF drugs was approximately 6 cases per 100,000,⁴⁷ although some studies have suggested that the rate in rheumatoid arthritis is higher than in the general population.⁴⁸ In one large patient registry, the estimated incidence of TB associated with infliximab in rheumatoid arthritis patients was in excess of 1000 per 100,000 person-years of exposure during the years 2000-2001.⁴⁹ In the United States, the rate was 52 per 100,000 person-years during the same time period.⁴⁷ Etanercept may be associated with a lower risk for TB reactivation than infliximab: 10 cases per 100,000 person-years of exposure with etanercept, versus 41 per 100,000 person-years with infliximab, according to an analysis of Food and Drug Administration data.⁵⁰ More recently, both British and French registries of biologic use have identified a greater risk for TB associated with the use of adalimumab and infliximab than with etanercept.^{51,52} Fewer data are available for the newer TNF antagonists, and comparisons are complicated by the widespread use of pretreatment screening instituted after the first agents in this class were approved for use. Monoclonal antibodies to TNF may play a greater role in destabilizing granulomata than

Figure 111-5 Tuberculous arthritis following total hip replacement. A sinus tract emerges from the scar following total hip arthroplasty for childhood destructive arthritis of unknown cause. The young man was originally from Vietnam.

TNF receptors. Nonetheless, similar precautions should be taken with any TNF antagonist, and all should be presumed to increase risk of new infection and reactivation of latent infection.

Other biologic agents may pose a lower risk for reactivation of TB because the mechanisms of action are not intimately involved with host defenses related to intracellular organisms. Animal studies have suggested that abatacept does not impair the ability of mice to respond to *M. tuberculosis*, but this has not been confirmed in humans.⁵³ Patients treated with abatacept and tocilizumab in clinical trials were prescreened with a TST and excluded if positive, thus making a direct comparison difficult. Little or no evidence indicates that B cells play a major role in containing TB, and no recommendation for TB screening is included in the labeling for rituximab.

Glucocorticoid use poses a significant hazard for patients with latent TB. Many mechanisms account for this effect, such as impairment of cellular immune responses and monocyte chemotaxis and function, including the monocyte's production of TNF. The use of glucocorticoids has been associated with a five times increased risk for the development of TB in a case-control study based on a large general practice database in the United Kingdom.⁵⁴ The risk appeared to be dose related but was seen even at the physiologic dose of prednisone 7.5 mg/day. Just as with anti-TNF therapy, the risk for TB was greatest early in the course of treatment. In a more recent study from France, prednisone given at 10 mg or more per day, but not at lower doses, was associated with an increased risk for developing TB.⁵²

Reactivation of TB in the face of anti-TNF therapy typically occurs within 6 months of treatment and often presents as extrapulmonary disease. Institution of a TB screening protocol in rheumatoid arthritis patients and treatment of latent TB before TNF antagonist administration resulted in a 78% decrease in active TB.⁵⁵ Strategies to treat latent TB infection that are tailored to the at-risk population can effectively and safely lessen the likelihood of active TB in patients treated with TNF antagonists. Indeed, it has been suggested that much of the blame for the development of active TB in this situation can be attributed to incomplete compliance with screening protocols.⁵⁶ Conversely, in a report of 84 patients at a single center treated with etanercept after demonstrating a positive purified protein derivative (PPD), no cases of active TB were seen during a mean of 2 years of follow-up, despite the fact that only 78 patients received prophylaxis, and 26 of those failed to complete the prescribed course.⁵⁷ Although screening for latent TB infection has reduced the incidence of active disease, false-negative TSTs can undermine such good intentions (see Table 111-1).

The approach to a patient with latent TB who needs anti-TNF therapy has not been standardized. Many authorities recommend that patients with positive TSTs and normal chest radiographs who have never been treated for TB receive at least 1 to 2 months of therapy before beginning an anti-TNF drug, if for no other reason than to be certain that they will be able to tolerate the full course of latent TB therapy. Appropriate regimens include 9 months of isoniazid or 4 months of rifampin. Patients discovered to have active TB should receive a complete course of standard

antituberculous therapy before any consideration is given to using an anti-TNF drug.

Although anti-TNF therapy and steroids stand out as particular risk factors for the development of TB, all rheumatic disease patients treated with immunosuppressive therapy that impairs cellular immunity should be considered at risk. This is especially true for the elderly, the malnourished, and immigrants from countries with high endemic rates of TB.

Rheumatic Disorders Precipitated by Treatment of Tuberculosis

A variety of rheumatic conditions may be precipitated by drugs used in the treatment of TB. These include drug-induced lupus caused by isoniazid (INH) and rifampin (RIF). As with other cases of drug-induced lupus, they are associated with positive antinuclear antibodies and the presence of antihistone antibodies. Typically, these patients follow a benign course, with reversal of disease after the drug is discontinued.

Arthropathy and tendinopathy have been described with the use of fluoroquinolones, especially ciprofloxacin and levofloxacin. Risk of tendon rupture (usually the Achilles tendon) is greatest in patients older than 50 years and increases with concomitant use of corticosteroids.

Pyrazinamide interferes with the renal tubular excretion of uric acid and has been associated with the development of hyperuricemia and gout in adults.

Some patients develop a paradoxical worsening of their condition upon initiation of antituberculous therapy. Such a development may raise questions about a flare of the underlying disease, especially if immunosuppressive therapy has been withdrawn in the face of infection. Symptoms include fever, malaise, weight loss, and increasing respiratory symptoms. The mechanism for such reactions is not completely understood but has been categorized within the spectrum of immune reconstitution inflammatory syndromes. Such reactions are more common in HIV patients and have also been seen in patients treated with infliximab following cessation of anti-TNF therapy.⁵⁸ Corticosteroids may ameliorate this response.

Reactive Immunologic Phenomenon in the Setting of Tuberculosis

A variety of reactive immunologic phenomena have been associated with *M. tuberculosis* infection. These are uncommonly found in clinical practice.

Poncet's disease is an aseptic inflammatory polyarthritis that occurs in the presence of active TB. Although any joints can be involved, the most commonly affected are the knees, ankles, and elbows.⁵⁹ The mechanism is thought to be similar to other forms of reactive arthritis secondary to remote infection. Most cases resolve after satisfactory treatment of the TB. A reactive arthritis has been described following intravesicular instillation of bacille Calmette-Guérin (BCG) vaccine for bladder cancer.⁶⁰

Other seldom encountered immune reaction patterns described with *M. tuberculosis* include erythema nodosum, erythema induratum, and amyloidosis (AA type).

DIAGNOSIS

Tuberculin Skin Test

The TST—also called the purified protein derivative (PPD)—has been in use for nearly a century and remains the most widely used screening test for TB. It is routinely administered in rheumatology offices that prescribe anti-TNF therapy. The test represents a crude mix of antigens from *M. tuberculosis* and is plagued by both false-positive and false-negative results. It is unable to distinguish latent infection from active disease and may be negative in the face of severe active TB. Corticosteroids (≥ 15 mg/day prednisone) may render the PPD negative in the face of latent TB. Elderly and malnourished patients may not exhibit a positive TST. Table 111-1 provides a partial list of causes of a false-negative TST that are of special interest to rheumatologists.

False-positive results may likewise occur in the case of infection with nontuberculous mycobacteria or previous BCG vaccine. PPD positivity degrades over time in BCG-vaccinated patients at a variable rate. The degree of positivity is influenced by a number of factors, including the number of BCG vaccinations and the number of subsequent PPD tests performed. Some patients may retain a response as long as 15 years after BCG vaccine. However, a PPD result of 20 mm or greater is rarely due to BCG. In addition, if faced with a high-risk situation, such as initiation of anti-TNF therapy, one probably should make a presumption of latent TB even if the diameter of induration measures as little as 5 mm.

The important message for rheumatologists is that the TST is an important but imperfect screening tool for latent TB infection, with sensitivity and specificity in the range of 70%. A negative TST should not eliminate the clinician's vigilance in monitoring patients who are being treated with anti-TNF therapy for reactivated or new-onset TB, especially in high-risk populations.

Imaging

Although imaging patterns suggestive of TB have been discussed, no pathognomonic skeletal radiographic features can establish the diagnosis. Early features on radiographs may be equivocal or nonexistent. Chest radiographs often are normal or fail to show features characteristic of TB.

Conventional radiography is generally a useful approach for defining bone destruction, extent of disease, and adjacent soft tissue lesions.⁵² MRI is more effective in identifying early disease; it may help distinguish TB from other infections and neoplasms and can aid in evaluating the extent of disease.^{9,61} Scintiscans with technetium and gallium may also be helpful in localizing bone and soft tissue lesions, but early false-negative findings are not uncommon.⁶² CT can be helpful in guiding diagnostic needle biopsy. Fine-needle biopsy is an acceptable alternative to core-needle biopsy and open biopsy for the diagnosis of osteoarticular TB in both the axial and the peripheral skeleton, and it has the advantage of obviating general anesthesia.^{63,64} Both CT and MRI may be helpful in monitoring therapy.⁶⁵

Culture

Nearly all species of *Mycobacteria* are slow growing, with *M. tuberculosis* being the slowest. Other bacteria may rapidly outgrow mycobacteria if the specimen is not inoculated on special isolation media. The small number of mycobacteria found in clinically infected areas further challenges the ability to confirm mycobacterial infection and accounts for the low yield of positive Ziehl-Neelsen staining (10% to 20%) in synovial fluid and other biologic fluids.

Synovial fluid and other bodily fluids are less likely than tissue to yield a positive culture. If a joint is suspected of harboring TB, a synovial biopsy should be obtained. Arthroscopically derived tissue yields higher positive cultures than needle biopsies do. CT-guided needle aspiration and biopsy can provide invaluable information in the case of spinal involvement. Characteristic features on tissue pathology, including caseating and noncaseating granulomata, may allow an early presumptive diagnosis of TB pending culture results, which may take 4 to 6 weeks to be finalized.

Advanced Diagnostic Testing

Interferon- γ Release Assays

The limitations of the traditional PPD skin test in terms of specificity and sensitivity in identifying latent TB have led to the development of new T cell-based testing. These assays measure the production of interferon- γ by whole blood mononuclear cells stimulated by specific *M. tuberculosis* antigens. The interferon- γ release assays (IGRAs) have become a useful test for latent TB and have good sensitivity and specificity for latent TB infection.^{66,67} These assays may prove particularly helpful in distinguishing TB from nontuberculous mycobacteria and in assessing patients who have had recent BCG vaccines. They also offer the opportunity to circumvent operator error with TST administration and do not require patients to return for a reading. IGRAs have replaced the TST in some centers for routine screening for latent TB infection.

The role of IGRAs in the diagnosis of latent TB infection in patients with immune-mediated inflammatory disorders before initiation of anti-TNF therapy remains unsettled.⁶⁸⁻⁷³ The weight of evidence suggests that IGRAs are more sensitive and more specific than TSTs in this patient population. Indeterminate results from IGRAs in this setting have ranged from 1.2% to 28.6%, raising concerns about the performance of the assay from center to center.^{74,75} Overall, agreement of IGRAs with the TST is poor owing to a lower proportion of positive TSTs. Positive IGRAs are more closely related to TB risk factors than are positive TSTs. Discordant IGRA-negative/TST-positive results are associated with prior BCG vaccination, and discordant IGRA-positive/TST-negative results are associated with corticosteroid therapy, suggesting that the former represents a false-positive TST and the latter represents a false-negative TST. Nevertheless, the meaning of a discordant result is uncertain enough that patients with a positive test result with IGRA or TST should be considered for therapy of possible latent TB infection.⁷⁶ Additional experience will

be required to provide confidence that a negative IGRA in the setting of a positive TST reliably excludes latent TB infection. If only one testing modality is utilized, one recent analysis found that use of an IGRA was more cost effective than use of the TST for patients being screened before receiving anti-TNF therapy.⁷⁷

IGRAs have also been studied in patients receiving anti-TNF therapy to identify previously undiagnosed (“hidden”) latent TB infection or newly acquired TB infection. However, currently no guidelines are available for monitoring for tuberculosis infection in patients on anti-TNF therapy. Rates of TST conversion in patients on anti-TNF therapy have been reported to be 33% and 37% from centers in Korea and Taiwan; corresponding rates of IGRA conversion were 14% and 11%, respectively, and appeared to better correlate with the risk of active tuberculosis.^{78,79} Pending formal guidelines, in regions where ongoing exposure to infectious tuberculosis may occur, routine monitoring of patients with TB on therapy—perhaps annually—is probably wise.

Nucleic Acid Amplification

Molecular diagnostics using nucleic acid amplification may be helpful in patients with low mycobacterial loads and may provide more rapid diagnosis. The presence of polymerase chain reaction (PCR) inhibitors, especially in extrapulmonary specimens, can lead to false-negative results. Despite more than a decade of experience, the role of nucleic acid amplification tests in diagnosing TB infection is still being defined. These assays must be interpreted with caution in extrapulmonary tissue specimens, and when the clinical suspicion of infection is low.⁸⁰⁻⁸² In a small cohort of patients with vertebral osteomyelitis, multiplex PCR testing of bone biopsy specimens demonstrated 90% sensitivity and 100% specificity for tuberculous infection, illustrating the potential for this technology to provide rapid and accurate diagnosis.⁸³

TREATMENT

Appropriate management of tuberculous infection of bones and joints is a complex and evolving process. Proper selection of antibiotic regimens and ongoing disease monitoring should involve co-management with an infectious disease consultant. Nonetheless, rheumatologists should be familiar with the basic treatment principles.

Treatment of *M. tuberculosis* infections that involve the musculoskeletal system consists of the same combination chemotherapy regimens that are effective in pulmonary TB. Treatment regimens for infections of the bone and spine are longer than those recommended for lung disease and other extrapulmonary sites. The longer courses for musculoskeletal disease have been based on poor tissue penetration into osseous tissues and higher rates of relapse.

Current guidelines on the treatment of TB published jointly by the Centers for Disease Control and Prevention, the American Thoracic Society, and the Infectious Diseases Society of America recommend a 6-month course of therapy for all sites except the bone (6 to 9 months) and the central nervous system (9 to 12 months).⁸⁴ Rifampin is the critical component that allows shorter-course therapy.

The standard approach to TB therapy (both pulmonary and extrapulmonary) in the United States currently includes four drugs to start: isoniazid, rifampin, ethambutol, and pyrazinamide—known as IREZ therapy. Once the bacillus is confirmed to be sensitive to INH, ethambutol can be discontinued. Pyrazinamide is administered for 2 months, and rifampin and INH are continued for the duration of therapy.

Longer courses of therapy are required for patients who are slow to respond. Radiographic features of mycobacterial disease may not change much after 6 months of treatment, and response to treatment is based mainly on clinical features, including reduction in pain, resolution of constitutional symptoms, and emergence of increased mobility. Longer courses are advised for cases of relapse and for resistant organisms.

Surgical intervention is seldom indicated for the initial management of osteoarticular TB. Possible exceptions at presentation include patients with advanced or progressive disease or spinal kyphosis of 40 degrees or greater. Multidrug-resistant tuberculosis may also provide a relative indication for surgical débridement. Patients who have extensive joint destruction and immobility after an adequate course of chemotherapy may be candidates for surgery.

Following successful antibiotic therapy, arthroplasty of the hip and knee may be undertaken and is usually successful. Recurrence of disease in the prosthetic joint is less likely if the surgery is performed years after the infection, and if the tissue obtained at surgery is culture negative. This may be impractical, however, when a patient is unable to ambulate following an adequate course of therapy. In such cases, TB therapy is continued through surgery and for at least 3 months postoperatively. If TB recurs in the prosthetic joint, it can sometimes be managed with antibiotic therapy alone. However, in many cases, removal of the prosthesis is necessary for complete resolution of infection.

The increasing incidence of drug-resistant TB complicates the selection of appropriate drugs.^{85,86} Primary mono-resistance to isoniazid occurs in about 7% of TB isolates in the United States. When identified, this does not substantially impact the treatment outcome. Multidrug-resistant TB (MDR-TB) refers to isolates that are resistant to isoniazid and rifampin. The rate of MDR-TB in the United States has been relatively stable for the past decade, at less than 1%. In other parts of the world, MDR-TB rates may exceed 6% for new cases and 30% in previously treated individuals. The treatment of MDR-TB is complex and often requires the use of multiple (often toxic) second-line agents for 18 to 24 months or longer. XDR-TB—that is, strains resistant to all first-line TB drugs and to at least three second-line agents—has been reported in at least 17 countries, with particularly high rates in Kazakhstan, Iran, and South Africa.⁸⁷ Options for treatment of XDR-TB are very limited, and risks of treatment failure and death are high.⁸⁸

Incomplete adherence to treatment is a particularly important risk factor for secondary drug resistance, and the likelihood of drug resistance increases following relapse after treatment. Directly observed therapy is strongly advocated to reduce the spread of infection and the frequency of drug-resistant TB.⁸⁹

OSTEOARTICULAR INFECTIONS CAUSED BY NONTUBERCULOUS MYCOBACTERIA

Nontuberculous mycobacteria (NTM) are ubiquitous in the environment, including soil, water, and animal reservoirs. They are not typically spread from human to human, and infections with these organisms have been reported with increasing frequency.⁹⁰ Although a vast majority of infections caused by these organisms are pulmonary, skin and soft tissue infections may be seen in normal hosts; children may develop a localized lymphadenitis.⁹¹ Osteoarticular infections are usually caused by direct inoculation of the organism or by spread of contiguous infection.⁹¹ Blunt trauma has been implicated as a risk factor in cases of vertebral osteomyelitis due to NTM.⁹² Immunosuppressed hosts may develop nontuberculous mycobacterial infections of the musculoskeletal system, but these infections are much less common than TB. In contrast to TB, nontuberculous infection is more likely to cause tenosynovitis, synovitis, or osteomyelitis and is less likely to cause spinal infection. A review identified only 31 cases of vertebral osteomyelitis due to NTM reported between 1965 and 2003.⁹³ Although more than 120 species of nontuberculous mycobacteria are known, most musculoskeletal infections are caused by *Mycobacterium marinum*, *Mycobacterium kansasii*, and *Mycobacterium avium-intracellulare* (also called *M. avium* complex, or MAC), but cases of musculoskeletal infection with *Mycobacterium haemophilum*, *Mycobacterium chelonae*, and *Mycobacterium xenopi* have also been reported.⁹⁴⁻⁹⁷

Three distinct patterns of musculoskeletal involvement have been reported: tenosynovitis, synovitis, and osteomyelitis.^{98,99} Tenosynovitis typically presents as chronic unilateral hand and wrist swelling (Figure 116A-C).¹⁰⁰ Synovitis typically presents as chronic indolent asymmetric swelling in a knee, hand, or wrist. A number of species have been associated with these syndromes, and the number isolated from immunosuppressed patients is growing.¹⁰ Predisposing factors, in addition to immunosuppression and direct inoculation, include environmental exposure and pre-existing joint disease.¹⁰¹

Musculoskeletal infections with atypical mycobacteria may be indistinguishable from *M. tuberculosis* infections, so that correct diagnosis usually requires tissue biopsy and culture. Synovial fluid, when attainable, is typically inflammatory, and a culture may be helpful only if specific mycobacterial cultures are requested. Identification of acid-fast bacilli on smear and granulomatous inflammation from a tissue biopsy specimen often provides direction for an appropriate microbiologic investigation, but histologic features do not consistently demonstrate granuloma formation. With a compatible clinical presentation and histologic findings, mycobacterial culture, including special techniques for *M. marinum*, should be requested. Direct amplification testing may be useful for more rapid identification of mycobacterial species in tissue specimens, but data from musculoskeletal cases are limited.^{81,102} In addition to mycobacteria, causes of granulomatous synovitis include fungi, brucellosis, sarcoidosis, inflammatory bowel disease, and nonmetallic foreign bodies. *Mycobacteria* other than *M. tuberculosis* are responsible for a significant proportion of these cases.¹⁰³

MAC has become the most common mycobacterial infectious agent affecting patients with HIV/AIDS, in

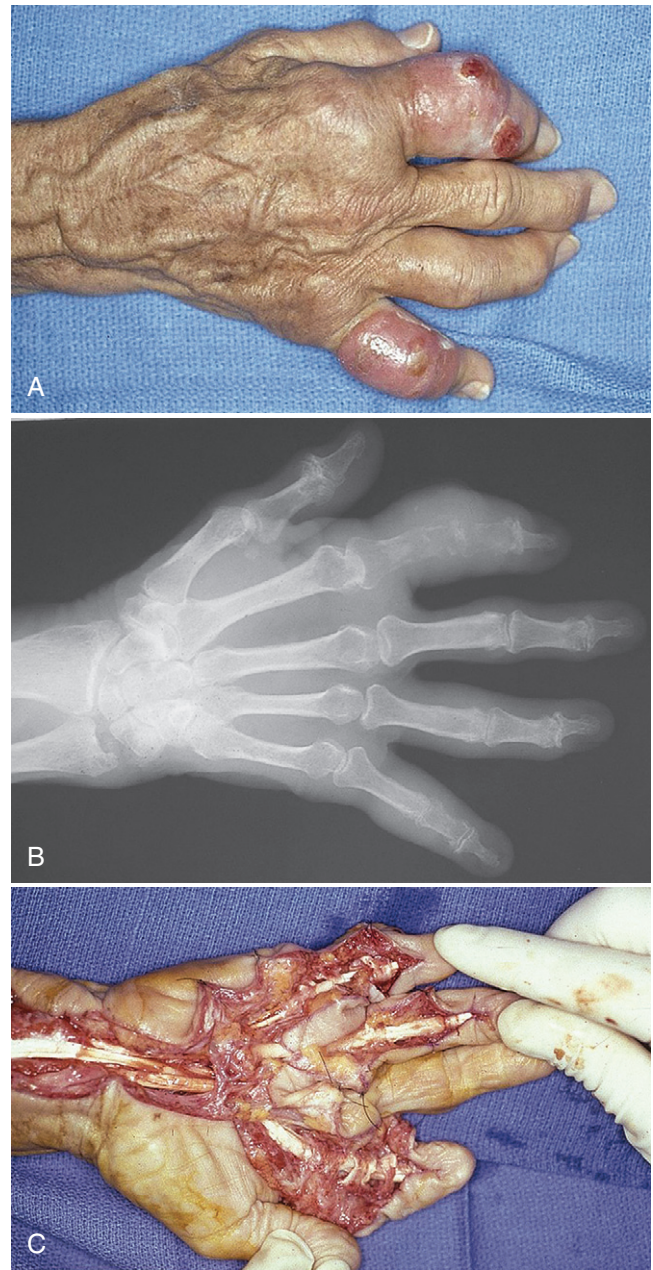

Figure 111-6 A, Hand demonstrating tenosynovitis and synovitis secondary to *Mycobacterium marinum*. B, Radiograph of the hand in A demonstrates joint destruction secondary to *M. marinum*. C, Hand depicted in A and B shows extensive tenosynovitis at the time of synovectomy.

whom it has a tendency to cause disseminated disease.¹⁰ Fortunately, a sharp decline in the incidence of MAC has been noted following the introduction of effective antiretroviral therapy and MAC prophylaxis.

Isolation of *M. tuberculosis* is always clinically significant. In contrast, when dealing with a nontuberculous mycobacterial isolate, the clinician must judge whether it is a contaminant, represents insignificant colonization, or is the cause of disease. Certain guidelines have proved useful in this respect^{43,101,104,105}:

- The illness should be consistent with one or more syndromes associated with mycobacterial infection.

- Other causes of disease, such as TB and fungal infection, should be excluded.
- The mycobacterial species isolated is one associated with human disease, the most significant being those that are not common environmental contaminants (*M. kansasii*, *M. marinum*, *M. simiae*, *M. szulgai*, and *M. ulcerans*).
- The site of isolation of the organism should favor true infection over contamination or colonization. (Isolation from bone biopsy, synovial tissue, or synovial fluid strongly suggests infection; isolation from the respiratory tract may represent infection or colonization.)
- Heavier growth suggests significant infection.
- Repeatedly positive cultures suggest significant infection.

Because laboratory identification of the organism and sensitivity testing may take weeks to months, initial therapy often includes multiple drugs to cover both TB and other mycobacteria. One common approach to initial empiric therapy is to link standard IREZ therapy for TB with clarithromycin until final culture results are available. The most recent American Thoracic Society guidelines for the treatment of nontuberculous mycobacteria were published in 2007.¹⁰⁶ Surgical débridement of infected tissue may play an important role in the treatment of selected patients, especially for resistant organisms. The most efficacious drugs remain controversial, prolonged treatment is often necessary, and relapses are not uncommon. As with TB, therapy customized to the individual patient is crucial with nontuberculous mycobacterial infection. The key to effective therapy lies in the unique characteristics of the culture and in the sensitivity of the particular isolate.

EMERGENCE OF NONTUBERCULOUS MYCOBACTERIAL INFECTION DURING THE TREATMENT OF RHEUMATIC DISEASE

No published data exist on the risk of nontuberculous mycobacterial infection in the setting of therapy with nonbiologic disease-modifying antirheumatic drugs, including methotrexate. The decision to interrupt or continue therapy in such instances should be made on a case-by-case basis and should involve an infectious disease specialist, with recognition that alternative treatments, such as steroids and biologics, may carry an even greater risk.

Nontuberculous mycobacteria are increasingly recognized as important pathogens in patients receiving anti-TNF therapy. Indeed, these infections now occur twice as frequently as TB in the United States, presumably because of the use of screening tests for the latter.¹⁰⁷ The complexity of these infections was illustrated by a recent review of 239 cases of nontuberculous mycobacterial infection reported to the MedWatch database, in which only 105 were established to be probable or confirmed according to established disease criteria.¹⁰⁸ The most commonly reported presentation was seen in elderly women with rheumatoid arthritis (RA), possibly because both nontuberculous mycobacterial infection and RA are common in this group; most patients were also taking concomitant steroids and/or methotrexate. Infections with several different species within this group

have been reported, with MAC being the most common. As with TB, the risk appears to be associated with all drugs in the class, rather than with a specific agent, although more infections have been reported with infliximab.¹⁰⁸ Extrapulmonary disease is a common finding and is unusual for these organisms. A paradoxical response to therapy, similar to that seen with TB, has been reported with treatment of MAC following infliximab.¹⁰⁹ Although cessation of anti-TNF therapy is appropriate following the development of an atypical mycobacterial infection, the safe reintroduction of etanercept during treatment of *M. marinum* has been reported.¹¹⁰

Managing the risk of nontuberculous mycobacterial infection in the setting of anti-TNF therapy can be challenging. Although screening has been helpful in reducing the risk of TB infection in this setting, no method of screening for atypical mycobacteria is currently available. Because these infections are more common in individuals with pre-existing pulmonary disease, clinicians may wish to consider more extensive evaluation of RA patients with bronchiectasis about to initiate anti-TNF therapy. Although MAC prophylaxis is recommended for HIV-positive patients with CD4 counts of 50 or lower, no experience with and no guidelines for such prophylaxis with anti-TNF therapy have been put forth. The complex nature of these infections has been further demonstrated by a case of *M. marinum* mimicking RA, with synovitis and subcutaneous nodules developing during infliximab therapy.¹¹¹

Fungal Infections of Bones and Joints

ERIC M. RUDERMAN • JOHN P. FLAHERTY

KEY POINTS

Fungi are an infrequent but clinically important cause of bone and joint infections.

These infections are often indolent in onset and may masquerade as other disorders.

Travel and immigration have affected the geographic localization of several important fungal infections, which may be seen in nonendemic areas.

Although diagnosis may be assisted by clinical presentation and serologic testing, examination and culture of infected tissue are critical.

New antifungal therapies have broadened the effective options, but choice of drugs, duration of treatment, and combined surgical débridement must be carefully considered to achieve optimal outcomes.

Immunocompromise including antirheumatic biologic therapies predisposes to fungal infections, often resulting in more acute and widely disseminated disease.

Screening and/or prophylactic therapy have not proven useful for patients on immunosuppressive therapy, so a high index of suspicion should be maintained when such patients present with an acute febrile illness.

Fungal infection is a relatively infrequent but important cause of osteomyelitis and arthritis. Fungal diseases that commonly cause osteomyelitis include coccidioidomycosis, blastomycosis, cryptococcosis, candidiasis, and sporotrichosis (Table 112-1). Fungal arthritis is less common and is most often associated with sporotrichosis, cryptococcosis, coccidioidomycosis, blastomycosis, candidiasis, and, occasionally, other species. The epidemiology of these fungal infections, their musculoskeletal presentations, and their treatment are considered in this chapter.

The epidemiology and clinical features of individual deep mycoses may suggest the diagnosis in some cases, but their indolent presentation, which often resembles that of other noninfectious diseases, may be misleading. Travel and immigration have blurred their geographic localization. Infection may be acute and overwhelming in immunocompromised patients, for whom disseminated fungal infections are a major risk. Anticytokine and other immunosuppressive treatments for rheumatic diseases, particularly those targeting tumor necrosis factor (TNF), are associated with disseminated fungal infection,^{1,2} as are acquired immunodeficiency syndrome (AIDS), pregnancy, and treatments for transplantation and malignancies,³ in some cases. For rheumatologists, disseminated fungal infections are an

important diagnostic consideration in some patients and must be considered before starting biologic treatments in those at risk; they may also complicate the clinical course of other arthritides. The presentation of fungal infections as a consequence of rheumatic disease therapy will also be considered in this chapter.

Fungal infections are generally diagnosed by histologic examination or culture of involved tissues. Improved biopsy techniques may assist the diagnosis, provided the possibility of fungal infection is considered and proper studies are requested. Synovial fluid leukocyte counts and culture results vary among fungal infections and in individual cases and may be misleading. Serologic testing may also assist in diagnosing and staging several fungal infections. Detecting fungal antigens and DNA in blood and tissue is now possible in some cases, but the clinical use of these methods is still under investigation.⁴

COCCIDIOIDOMYCOSIS

The soil fungi *Coccidioides immitis* and *Coccidioides posadasii* generally cause a primary respiratory illness after spores are inhaled. A self-limited acute pneumonia may result, associated with systemic manifestations such as arthralgia and erythema nodosum (valley fever), but infection is often unapparent and only infrequently becomes chronic or disseminated.⁵ Coccidioidomycosis is endemic to the southwestern United States and areas of Central and South America, but cases are increasingly diagnosed in nonendemic areas because of travel, infection from fomites, and reactivation of remote infection. Cases increase when soil is disturbed and in windy conditions. Direct human-to-human transmission is rare. Extrapulmonary infection is almost always caused by hematogenous spread from an initial pulmonary focus. The bones and joints are frequent sites of dissemination, particularly in immunocompromised hosts.

Septic arthritis of the knee is common, generally arising from direct infection of the synovium. Other joint infections are caused by spread from a contiguous osteomyelitis involving the vertebrae, wrists, hands, ankles, feet, pelvis, and long bones.⁶ The onset is characterized by gradually increasing pain and joint stiffness, with little swelling but early radiographic changes. In one series, arthritis was the only manifestation of disseminated coccidioidomycosis in 51 of 57 patients and was an aspect of more generalized disease in the remaining 6 patients.⁷

Diagnostic confusion is common in osteoarticular coccidioidomycosis because of the delayed dissemination (months to years) after primary infection and because of atypical clinical presentations. The criteria for diagnosis

include compatible clinical features, serologic studies, histologic examination, and culture. Early infections, often before systemic spread, are associated with a positive antibody precipitin test that detects immunoglobulin (Ig) M antibody. Complement fixation serologic values detecting IgG antibodies are in a range indicative of disseminated disease in a majority of patients and show a significant decrease with effective treatment. Serologic testing for *Coccidioides* may have negative results early in the infection and in immunosuppressed patients. A specific enzyme immunoassay (EIA) to *Coccidioides* galactomannan antigen in urine has shown promise in the diagnosis of severe coccidioidomycosis infection.^{8,9} The definitive diagnosis is most commonly made by the demonstration of granulomatous synovitis and typical spherules in a biopsy specimen, confirmed in some cases by positive culture and direct amplification testing. Synovial fluid, when obtainable, does not necessarily demonstrate septic leukocyte counts and may have a lymphocyte predominance. Synovial fluid is rarely culture positive; culture of synovial tissue may be more helpful. Radioisotope bone scans may be helpful to identify areas of infection.¹⁰

With early diagnosis of effusive synovitis, antifungal treatment alone is appropriate. Treatment is usually initiated with oral azole antifungal agents, most commonly fluconazole or itraconazole.¹¹ Amphotericin B is recommended for alternative therapy, especially if lesions are appearing to worsen rapidly and are in particularly critical locations such as in vertebral osteomyelitis. Lipid formulations of amphotericin B have demonstrated less nephrotoxicity and infusion-related side effects than conventional deoxycholate amphotericin B and may be given at doses higher than those tolerated with conventional amphotericin, but they have never been formally studied in clinical trials. With more widely disseminated infection or involvement of critical areas such as the spine, as well as in high-risk hosts, the choice and duration of treatments are often complicated. Factors that favor surgical intervention are large size of abscesses, progressive enlargement of abscesses or destructive lesions, presence of bony sequestrations, instability of the spine, or impingement on critical organs or tissues (e.g., epidural abscess compressing the spinal cord).^{7,12,13} Newer antifungal agents such as voriconazole and posaconazole show promise as alternative therapy.^{11,14-16} Long-term prophylaxis with fluconazole can limit the risk for reactivation in immunosuppressed patients.

Coccidioidal synovitis may also occur as a consequence of immune complex-mediated inflammation, a presentation that may complicate either primary pulmonary or

disseminated disease and is typically polyarticular. It is accompanied by fever, erythema nodosum or multiforme, eosinophilia, and hilar adenopathy. It abates in 2 to 4 weeks.^{5,17}

BLASTOMYCOSIS

Blastomycosis, caused by *Blastomyces dermatitidis*, is endemic in the north-central and southern United States. Infection most commonly produces sporadic or clustered cases of pulmonary disease and is induced by exposure to soil or dust containing decomposed wood and, presumably, contaminated with the organism.¹⁸ Affected individuals do not appear to have any distinguishing or predisposing characteristics except for exposure to the organism during work or recreation. Clinical presentation includes high fever and other constitutional symptoms, pulmonary and skin involvement, and a significant mortality rate; leukocytosis and an elevated sedimentation rate are frequently seen.¹⁹ Bone pain, swelling, and soft tissue abscesses are the most common manifestations of osteoarticular disease.²⁰ Hematogenous dissemination is common; skin disease and osteoarticular disease occur most frequently. Bone involvement occurs in 25% to 60% of disseminated cases, and arthritis is estimated to occur in 3% to 5%.¹⁹ In a study of 45 patients with skeletal blastomycosis, 41 had osteomyelitis while 12 presented with septic arthritis.²⁰ The skeletal areas most commonly affected are the long bones, vertebrae, and ribs (Figure 112-1).²¹⁻²³

Arthritis is usually monoarticular in the knee, ankle, or elbow but may rarely be polyarticular.^{19,24} Joint infection is an isolated skeletal disorder in only a few cases; joint radiographs more commonly show punched-out bone lesions (Figure 112-2A). Synovial fluid is commonly purulent, and organisms are evident on microscopic examination, as well as by culture. The synovial histologic examination shows epithelioid granulomas with budding yeast forms (Figure 112-2B). The diagnosis is also commonly made from involved nonarticular sites. Urinary antigen testing appears to be sensitive but may be falsely positive in patients with other endemic fungal infections.²⁵ For moderately severe or severe disease, treatment with amphotericin B for 1 to 2 weeks or until improvement is noted, followed by oral itraconazole for a total of at least 12 months, is recommended. For mild to moderate disease, oral itraconazole for 12 months is recommended. Serum levels of itraconazole should be determined after the patient has been on treatment for at least 2 weeks, to ensure adequate drug exposure.^{18,26-28}

CRYPTOCOCCOSIS

Cryptococcus neoformans, the fungus causing cryptococcosis, is geographically ubiquitous and is found in pigeon feces; a related species, *Cryptococcus gattii*, is associated with certain types of eucalyptus trees in tropical climates and has been associated with an ongoing outbreak of disease on Vancouver Island and surrounding areas of Canada and the northwestern United States. It is a common pathogen only in association with defects in cell-mediated host defense including human immunodeficiency virus (HIV) infection, transplantation, lymphoreticular malignant

Figure 112-1 **A**, Blastomycosis osteomyelitis of a rib and chest wall. **B**, Computed tomography scan appearance. Primary infection in the blood may spread to the skeleton.

neoplasms, TNF antagonist treatment,^{29,30} and corticosteroid therapy.

Cryptococcosis varies in acuity, usually affecting the lungs in its primary form, but it sometimes disseminates hematogenously to a wide variety of sites including the central nervous system and skin. Although bone infection is common, causing osteolytic lesions in 5% to 10% of cases, articular involvement is rarely reported.^{31,32} Bone lesions may be confused with metastatic neoplasm (Figure 112-3).

Cryptococcal arthritis is an indolent monoarticular arthritis in about 60% of reported cases and a polyarthritis in the remainder.^{33,34} The knee is most commonly involved. A single case of tenosynovitis with carpal tunnel syndrome has been recognized. The majority of cases reported from the pre-AIDS era also demonstrated radiographic evidence of periarticular osteomyelitis. These patients were young adults, did not have debilitating disease or other evidence of dissemination, and had pulmonary involvement in only 50% of cases. Synovial tissue showed acute and chronic synovitis, multinucleate giant cells, prominent granuloma formation, and large numbers of budding yeast with special stains. Most recently reported cases are associated with immunosuppression and disseminated infection. Interestingly, osteoarticular cryptococcal infections have been linked to sarcoidosis, although it is unclear whether this association relates to the immunologic impact of the sarcoidosis or to the immunosuppressive therapies used to treat it.³⁵ Serum cryptococcal antigen testing appears to be sensitive, in part because osteoarticular infection results from hematogenous dissemination. The choice of treatment for cryptococcal disease depends on both the anatomic sites of involvement and the host's immune status, with amphotericin B and fluconazole being considered most effective.^{34,36} 5-Flucytosine is typically added to amphotericin B or fluconazole for the first 2 to 4 weeks (induction therapy) in cases of severe cryptococcal infection.³⁷

CANDIDIASIS

Candida species are widely distributed yeasts. *Candida albicans* is a normal commensal of humans, and other species can probably live in nonanimate environments such as soil. Since the advent of antibiotic therapy in the 1940s, and related to the common use of immunosuppression and parenteral lines, candidiasis has been responsible for an increasing incidence of mucocutaneous and deep-organ infections.³⁸ Osteomyelitis, though rarely reported, is a potentially serious complication of hematogenous dissemination in both adults and children.^{39,40} It may also occur from direct tissue inoculation during surgery or by injection of contaminated heroin,⁴¹ and bone infection may emerge after successful amphotericin B treatment of other sites. Infection is commonly located in two adjacent vertebrae or in a single long bone. Surgical inoculation has occurred in the sternum, spine, and mandible. A few patients have had multiple sites of involvement. Candidal prosthetic joint infections may also occur as a late consequence of total joint replacement.⁴²

The clinical presentation is localized pain. Other symptoms and laboratory abnormalities vary. Bone changes of osteomyelitis are commonly demonstrated in radiographs of the symptomatic site. The diagnosis is established when culture of involved bone obtained by either open or needle biopsy has identified a variety of *Candida* species. Use of direct amplification testing has been reported.⁴³ Treatment with azoles (fluconazole, itraconazole, voriconazole, or posaconazole); echinocandins (casposungin, micafungin, or anidulafungin); or amphotericin B formulations may be effective.^{44,45} Species identification and susceptibility testing assist antifungal therapy selection. For example, *Candida glabrata* frequently demonstrate reduced susceptibility to azole antifungal agents and amphotericin but remain susceptible to echinocandins; *Candida krusei* are often resistant

to azoles and may show reduced susceptibility to amphotericin but also remain susceptible to echinocandins; *Candida lusitanae* are often resistant to amphotericin; and *Candida parapsilosis* may demonstrate reduced susceptibility to echinocandins.⁴⁵ The use of surgical débridement must be individualized. With vertebral involvement but no neurologic complications, medication alone has been effective.

Candidiasis is an uncommon cause of monoarticular arthritis.⁴⁶ *C. albicans* is the most common pathogen, although septic arthritis due to other candidal species has been reported.⁴⁷ Reported cases commonly involve a knee, occur in the context of multifocal extra-articular *Candida* infection, and are accompanied by constitutional symptoms. Both children and adults have been affected. Predisposing conditions include gastrointestinal and pulmonary disorders, narcotic addiction, intravenous catheters, leukopenia, immunosuppressive treatment (including TNF antagonists), broad-spectrum antibiotics, and corticosteroids. Some involved joints were previously affected by arthritis, and infection has followed arthrocentesis in isolated cases. In most cases, radiographs reveal coincident

Figure 112-2 Blastomycosis joint infection. **A**, Radiographs commonly show punched-out bone lesions. **B**, Synovial histology shows epithelioid granulomas with budding yeast forms.

Figure 112-3 Cryptococcosis (torulosis). Discrete osteolytic foci with surrounding sclerosis and, in some places, periosteal reaction are seen (arrows). This involvement of bone protuberances such as the calcaneus is not unexpected in this disease. The resulting appearance simulates that of other fungal diseases, especially coccidioidomycosis, as well as neoplastic disorders. (From Resnick D: *Diagnosis of bone and joint disorders*, ed 3, Philadelphia, 1995, WB Saunders, p 2507.)

osteomyelitis. Synovial fluid leukocyte counts may vary; *Candida* species have been cultured from synovial fluid in all cases but are not commonly identified on smear. Histologic studies of synovium show nonspecific chronic inflammation rather than granulomas.

SPOROTRICHOSIS

Sporotrichosis is caused by *Sporothrix schenckii*, a saprophyte found widely in soil and plants. Infection in humans occurs through inoculation of the skin or, rarely, inhalation into the respiratory tract; it is a source of infection among agricultural workers in tropical and subtropical areas. It most commonly involves the skin and lymphatics but may disseminate from the lungs to the central nervous system, eyes, bones, and joints.⁴⁸ In immunocompetent hosts, a single site is typically involved; in immunocompromised hosts including patients on anticytokine therapy, multifocal disease may occur.⁴⁹

In contrast to the relatively common occurrence of skin infection, articular sporotrichosis is a rare disorder.^{50,51} In 84% of patients in one series, there was no accompanying skin involvement, suggesting entry through the lungs. Sporotrichosis most often occurs in individuals with a chronic illness that alters host defense such as alcoholism or a myeloproliferative disorder. *Sporothrix* arthritis is most often indolent and infects a single joint or multiple joints in equal proportions. The knee, hand, wrist, elbow, and shoulder are most frequently involved; hand and wrist involvement distinguishes this from other fungal arthritides. Articular infection shows a propensity to spread to adjacent soft tissues,

forming draining sinuses. Constitutional symptoms are unusual.

Radiographic changes vary from juxta-articular osteopenia to the commonly observed punched-out bone lesions. When it can be obtained, synovial fluid is inflammatory. Synovitis is characterized on gross evaluation by destructive pannus and on microscopic examination by granulomatous histologic features or, less frequently, by nonspecific inflammation. Organisms are difficult to identify in tissue, and the diagnosis is often made by positive culture of joint fluid or involved tissue. Incubation at room temperature assists growth of the mycelial phase of *S. schenckii*. Serologic testing is not useful in the diagnosis of sporotrichosis. In a small number of cases, sporotrichosis may disseminate to cause a potentially fatal infection characterized by low-grade fever, weight loss, anemia, osteolytic bone lesions, arthritis, skin lesions, and involvement of the eyes and central nervous system.⁵²⁻⁵⁵ These infections occur in immunosuppressed patients with either hematologic malignancies or HIV infection.

In 44 cases reported in 1979, treatment was optimal with combined joint débridement and high-dose intravenous amphotericin B (11 of 11 cured) and slightly less effective with amphotericin alone (14 of 19 cured).⁵⁰ More recently, itraconazole has proven effective for initial therapy of most patients,⁵⁶ with amphotericin B being reserved for those with extensive involvement and for itraconazole failures. In contrast, fluconazole has demonstrated only modest success in osteoarticular sporotrichosis.^{57,58} Long-term suppressive therapy with itraconazole may be required for patients with AIDS.⁵⁶

ASPERGILLOSIS

Aspergillus species are ubiquitous, but infection occurs only rarely in immunocompetent individuals. In contrast, invasive infection is an important life-threatening complication in immunocompromised adults and children.⁵⁹⁻⁶¹ It may spread directly from the lung to adjacent vertebrae, disk spaces, and ribs (more often in children) or through the bloodstream (Figure 112-4).⁶²⁻⁶⁴ Rare cases of monoarthritis with adjacent osteomyelitis are also reported. The knee is the most commonly involved joint. The organism may be observed in infected tissue (see Figure 112-4B). The galactomannan EIA has been validated as a surrogate marker for invasive aspergillosis and the (1→3)-β-D-glucan assay may similarly provide support for the diagnosis of invasive fungal infection. Treatment with combined surgical débridement and antifungal therapy is an ongoing challenge.^{60,63,65} Voriconazole has proven superior to amphotericin for the treatment of invasive aspergillosis and is now recommended for initial therapy.^{65,66} Liposomal amphotericin B, posaconazole, caspofungin, and micafungin have demonstrated efficacy in salvage situations.⁶⁷ Combination therapy has not demonstrated clear improvement in outcomes over monotherapy.

HISTOPLASMOSIS

Histoplasma capsulatum is a soil fungus that causes endemic disease in the midwestern and southeastern United States.^{33,68} Bone and joint involvement is rare but has been reported in the knee, wrist, and ankle. Immunosuppression

Figure 112-4 Aspergillosis vertebral osteomyelitis and diskitis. **A**, *Aspergillus* may spread directly from the lung to adjacent vertebrae, disk spaces, and ribs (more often in children) or through the bloodstream. **B**, Infected tissue may show characteristic organisms.

including the use of TNF antagonists predisposes to disseminated histoplasmosis in adults and children, which may be confused clinically with sarcoidosis, tuberculosis, and reactive inflammatory conditions.^{69,72} Diagnosis depends on appropriate use of fungal staining and culture methods, antigen detection, and serologic antibody testing.⁷³ A case report emphasizes the rare occurrence of fungal prosthetic joint arthritis.⁷⁴ The more common osteoarticular involvement with histoplasmosis is a hypersensitivity syndrome accompanying acute pulmonary infection; it is characterized by self-limited polyarthritides, erythema nodosum, and erythema multiforme. Liposomal amphotericin B followed by itraconazole is the preferred treatment for severe infection and itraconazole for less severe cases.^{68,75,76}

SCEDOSPORIOSIS

Scedosporium species are environmental molds that have recently been identified as fungal pathogens in both immunocompetent and immunocompromised hosts. They may cause focally invasive and disseminated infection after cutaneous inoculation. *Scedosporium prolificans* has a predilection for bone and cartilage, leading to both septic arthritis and osteomyelitis. Infections are difficult to eradicate with surgery and antifungal agents, and the organism is resistant to amphotericin.^{77,78} Case reports suggest improved infection control with voriconazole or voriconazole combined with terbinafine.⁷⁹⁻⁸¹

TREATMENT OF FUNGAL INFECTION

Antifungal chemotherapy has improved over the past several decades, first with the introduction of amphotericin B and then with the oral antifungal agents flucytosine, ketoconazole, fluconazole, and itraconazole. More recent advances include the development of less toxic formulations of amphotericin B, liposomal amphotericin B, and amphotericin B lipid complex. Voriconazole and posaconazole, which are broad-spectrum azole antifungals, have demonstrated improved activity against aspergillosis and mucormycosis, respectively. The echinocandin antifungal agents caspofungin, micafungin, and anidulafungin have emerged as alternative therapies for aspergillosis and as the treatments of choice for some *Candida* infections. For detailed treatment guidelines, several excellent reviews are available.⁸²⁻⁹¹ In choosing an appropriate drug (Table 112-2) and course of treatment, the clinician must consider the infecting agent, clinical manifestations of the disease,

immune status of the host, antimicrobial resistance, drug side effect profile, and direct and indirect costs of treatment. Treatment has become more complex because of immune system compromise in infected patients being treated for transplant rejection, autoimmune disorders, malignant disease, and AIDS.⁹²

Itraconazole has become the first choice for treatment of the endemic mycoses—blastomycosis, histoplasmosis, and sporotrichosis. A loading dose of itraconazole of 200 mg three times a day for 3 days is recommended, followed by 200 mg to 400 mg daily. Absorption of itraconazole is unpredictable, and blood levels of itraconazole should be measured to ensure adequate drug exposure. Absorption of itraconazole requires stomach acid, so concurrent administration of drugs that reduce the acidity of the stomach such as proton pump inhibitors and H₂ blockers should be avoided. At least 6 months of treatment is required, and some patients may need up to a year of therapy. For cryptococcosis, fluconazole is the recommended azole.^{34,36} Amphotericin B is the preferred drug for meningeal and life-threatening infections. Specific treatment protocols and detailed side effect profiles are presented in reviews,⁸²⁻⁹¹ Infectious Diseases Society of America guidelines,^{11,28,37,45,67,76} and infection-specific references (see Table 112-2).

FUNGAL INFECTION AS A CONSEQUENCE OF ANTIRHEUMATIC THERAPY

Many of the same fungal infections associated with osteoarticular disease may cause infection in patients treated with antirheumatic therapy, particularly biologic therapy. Animal models of infection point to an important role for TNF in host defense against many of these organisms including *Aspergillus*,⁹³ *Candida*,⁹⁴ *Cryptococcus*,^{95,96} *Coccidioides*,⁹⁷ and *Sporothrix*.⁹⁸

Coccidioidomycosis infection following TNF antagonist therapy has been reported in endemic areas in the southwestern United States. In the largest published series, 12 of 13 cases followed therapy with infliximab and 1 was associated with etanercept.⁹⁹ All but two of these cases were believed to represent new infection rather than reactivation. In one medical center included in this series, the relative risk of coccidioidomycosis infection was 5.23 with infliximab therapy compared with other antirheumatic therapy. In all cases, coccidioidomycosis infection developed in the absence of other known risk factors including diabetes, pregnancy, and HIV infection. Coccidioidomycosis infection has also been reported in nonendemic areas, presumably as a consequence of fomite exposure.¹⁰⁰

Disseminated histoplasmosis infections have been reported following TNF antagonist therapy in endemic areas in the Ohio-Mississippi River valley regions of the central United States; as with coccidioidomycosis infections, these have been reported more frequently following infliximab therapy than with the other agents.⁶⁹ The reason for the larger number of cases with infliximab is unclear; possibilities include a unique mechanism of action for infliximab, larger numbers of patients treated, patient selection, concomitant immunosuppressive therapy, or some combination of all of these. In most cases, patients

Table 112-2 Drug Treatment of Osteoarticular Mycotic Infections

Infection	Drug Recommended	Infection-Specific References
Coccidioidomycosis	Itraconazole	3, 7, 12, 13
Blastomycosis	Itraconazole	18, 27, 117
Cryptococcosis	Fluconazole	34, 36, 117
Candidiasis	Fluconazole	44-46, 117, 118
Sporotrichosis	Itraconazole	50, 57, 58
Aspergillosis	Voriconazole	61, 64, 117
Histoplasmosis	Itraconazole	68, 75
Scedosporiosis	Voriconazole	77, 80, 81

developing disseminated histoplasmosis with TNF antagonist therapy have been taking additional immunosuppressive therapy. Patients typically present with cough, dyspnea, fever, and malaise and can rapidly become quite ill. Histoplasma antigen may be identified in the urine in 92% of cases with disseminated histoplasmosis, and this test may assist rapid diagnosis.⁷¹ Exposure to *Histoplasma* may result in asymptomatic latent infection; it has been difficult, however, to determine whether symptomatic infections following TNF antagonist therapy represent reactivation or new infection. Both pulmonary and disseminated infections with cryptococcal infections have been reported with TNF antagonist therapy, as have infections with *Aspergillus*, *Candida*, *Scedosporium*, and *Sporothrix*.^{1,29,49,101-104} Fungal infections have not been reported as a consequence of abatacept or rituximab therapy in rheumatic diseases. Whether this relates to decreased risk with these agents or smaller numbers of patients treated remains to be seen.

Pneumocystis jiroveci pneumonia (PCP) is caused by a fungus originally classified as a protozoan (*Pneumocystis carinii*). PCP, an opportunistic infection seen in association with HIV infection, has been reported with a number of antirheumatic therapies including cyclophosphamide and low-dose methotrexate, often in combination with corticosteroid therapy.^{105,106} Interestingly, PCP as a consequence of low-dose methotrexate therapy has been reported as a particular concern in Japan, where the prevalence of asymptomatic carriage of *Pneumocystis* has been reported to be as high as 18.8% in the elderly.¹⁰⁷ These same authors have suggested that polymerase chain reactive (PCR) testing may identify carriers at increased risk for PCP during therapy.¹⁰⁸ The use of biologic therapy including rituximab¹⁰⁹ and TNF antagonists¹¹⁰ has been associated with the development of PCP. PCP presents as fever, dry cough, and dyspnea. The clinical presentation in patients receiving immunosuppressive therapy is typically more acute than in HIV-associated cases. Organisms may be identified in sputum from HIV patients but are seen less commonly in rheumatologic patients; presumptive diagnosis may be made on the basis of PCR testing for *P. jiroveci* DNA. Elevated serum levels of β -D-glucan, a common component of fungal cell walls, may aid in the diagnosis. One series of 21 patients identified older age, pre-existing pulmonary disease, higher corticosteroid doses, and low serum albumin and IgG levels as potential risk factors for PCP in patients treated with infliximab.¹¹⁰ Chest radiographs may show diffuse infiltrates, while CT scans demonstrate ground-glass opacities (Figures 112-5 and 112-6); radiographic findings may be difficult to distinguish from methotrexate pneumonitis. Treatment includes supplemental oxygen and trimethoprim/sulfamethoxazole (TMP/SMX) or pentamidine isethionate. High-dose corticosteroids are commonly used as adjunctive therapy in the treatment of HIV patients with PCP but are less well studied in patients taking immunosuppressives.

PCP infection is also of concern with nonbiologic immunosuppressive therapy. In particular, the use of cyclophosphamide to treat systemic lupus, vasculitis, and other autoimmune diseases has been associated with a risk of developing PCP, although the overall risk appears to be low. In a recent review of published data on 76,156 cases of systemic lupus erythematosus treated with cyclophosphamide, the risk of PCP was 15.88 per 10,000 patients, or

Figure 112-5 Chest radiograph showing diffuse interstitial infiltrate in a patient with *Pneumocystis jiroveci* pneumonia,

0.158%.¹⁰⁵ Potential risk factors include high-dose corticosteroid use, lymphopenia (especially low CD4 counts), renal disease, and overall high disease activity.^{105,111} Vasculitis patients with pulmonary involvement may be at increased risk, and diagnosis may be difficult in both these patients and lupus patients with pulmonary disease. Unfortunately, there are no published guidelines to address the use of PCP prophylaxis in autoimmune diseases or a clear consensus regarding the standard of care in this situation. Recent clinical trials in vasculitis have routinely employed PCP prophylaxis as part of the protocol, suggesting it is becoming the standard of care.¹¹² Two recent surveys of U.S. rheumatologists, however, found that just 50.4% and 69.5%, respectively, routinely prescribed prophylactic antibiotics.^{105,113} Academic rheumatologists and more recent graduates are more likely to prescribe prophylactic therapy. TMP/SMX appears to be more effective than dapsone or aerosolized

Figure 112-6 Computed tomography scan of the chest demonstrating ground-glass opacity in a patient with *Pneumocystis jiroveci* pneumonia.

pentamidine, despite an apparent increased risk of sulfonamide allergy in the lupus population.^{114,115} There are no consistent standards, or recommendations, for the use of prophylaxis for fungal infection other than *Pneumocystis*.

Given the risk of fungal infection with biologic therapy, careful patient selection for these compounds is understandably important. Patients with a history of fungal infection or those with significant exposure to these organisms should receive these drugs only when alternatives are not available or appropriate. Patients should be cautioned to minimize exposure to sources of infection during therapy (e.g., avoid exposure to histoplasmosis in old buildings [demolition, remodeling, cleaning], chicken coops, bird roosts, wood piles, or caves [spelunking]) and avoid exposure to outdoor dust in regions endemic for coccidioidomycosis. There is, as yet, no practical role for screening for latent infection or for prophylactic therapy.¹¹⁶ Serum IgG and IgM antibody titers may be elevated in patients who have had exposure to *Coccidioides*. Antibody titers normalize 3 to 6 months after initial exposure, however, rendering these tests unsuitable for identifying distant infections. Delayed-type hypersensitivity testing, which may help identify older infections, is not readily available in the United States. Moreover, most coccidioidomycosis infections seen in this situation appear to represent acute infection rather than reactivation. Chest radiographs may identify calcified granulomas consistent with prior histoplasmosis infection, but this is a nonspecific finding. In Japan, it has been suggested that TMP/SMX therapy may normalize PCR testing in asymptomatic *P. jirovecii* carriers treated with methotrexate and that this might reduce the risk of developing pneumonia, but this has not been studied in a U.S. population.¹⁰⁸ The lack of useful screening tests makes early recognition of infection and institution of therapy critical. Indeed, the U.S. Food and Drug Administration has mandated a “black box” warning regarding the risk of fungal infections on the product labels of TNF antagonists, reflecting the potentially fatal consequences of delayed recognition of such infections.

**KEY POINTS**

With patients with human immunodeficiency virus (HIV) living longer as a result of more effective and available treatments, the challenges of HIV-associated rheumatic manifestations are growing.

Certain diseases seem to be particular to HIV infection (i.e., HIV-associated arthritis, diffuse infiltrative lymphocytosis syndrome [DILS], HIV-associated polymyositis).

Other diseases, specifically CD4-mediated diseases such as rheumatoid arthritis and systemic lupus erythematosus, tend to go into remission with disease activity and to flare with antiretroviral treatment.

Effective antiretroviral therapy has resulted in certain diseases (i.e., DILS, late opportunistic infections) decreasing in prevalence but also is associated with new side effects (e.g., osteonecrosis, myopathy, rhabdomyolysis).

With immune reconstitution after antiretroviral therapy, a new spectrum of autoimmune and autoinflammatory disease has emerged requiring special attention.

In the years since acquired immunodeficiency syndrome (AIDS) was initially described in 1981, the human immunodeficiency virus (HIV) pandemic has become one of the leading global health crises. According to new data in the Joint United Programme on HIV/AIDS (UNAIDS) 2008 report, the AIDS epidemic seems to be slowing down globally, but new cases are continuing to increase at alarming rates in certain regions, such as southern Africa, eastern Europe, and central and eastern Asia. An estimated 33 million people worldwide are living with HIV (Figure 113-1). Approximately 2.7 million people became newly infected with HIV in 2007, and 2 million people died.

Progress in dealing with the HIV epidemic, including progress in education and in public health awareness, has undoubtedly influenced the decrease in prevalence seen among young people in some countries in recent years. As availability of newer treatment strategies and better access to health care result in increased life expectancy in the next decade, it is expected that HIV infection will be managed increasingly as a chronic illness, and complications such as musculoskeletal and rheumatic conditions associated with HIV infection and its treatment are expected to increase (Tables 113-1 and 113-2).

Among the rheumatologic disorders, clinicians face the challenge of treating potentially disabling inflammatory disorders with immunosuppressive therapy in the face of ongoing viral-induced immunocompromise. Diagnosing

infection is especially important in an immunocompromised patient because the probability of an opportunistic infection as a cause for a musculoskeletal complaint increases with advancing stages of the patient's HIV disease. At early stages ($CD4^+$ count $>300/\mu L$), opportunistic infections are unlikely, although bacterial infections (especially tuberculosis) still can occur. There should be a very high threshold for using immunosuppressive drugs in this population.

HIV-ASSOCIATED BONE AND JOINT DISEASE

HIV-Associated Arthralgia

More than 5% of HIV-positive patients may have otherwise unexplained arthralgia. Arthralgias and myalgias also form a part of the constitutional symptoms of HIV seroconversion. Whether arthralgia can be attributed to circulating viral and host immune complexes owing to HIV infection per se or to other infections (e.g., hepatitis C) has not been determined. The pathogenesis is unclear but may involve cytokines or transient bone ischemia.¹ However, patients presenting with arthralgia alone rarely progress to inflammatory joint disease. The most appropriate treatment consists of non-narcotic analgesics and reassurance.

Painful Articular Syndrome

Painful articular syndrome is a self-limited syndrome lasting less than 24 hours, associated with few objective clinical findings, and characterized by severe bone and joint pain.² It occurs predominantly in the late stages of HIV infection. Its cause is unknown, and no evidence of synovitis has been found in these patients. The knee is most commonly affected, but the elbow and shoulders also can be involved. Radiographic features are nonspecific; occasionally, periarticular osteopenia is seen. Treatment is symptomatic.

HIV-Associated Arthritis

The first reports of a seronegative arthritis associated with HIV infection appeared in 1988, with frequencies of 12%. HIV-associated arthritis seems to be most common in sub-Saharan Africa, where HIV infection is pandemic. In the Congo, where the seroprevalence of HIV infection is 7% to 8%, AIDS is the leading cause of aseptic arthritis (60% of cases).³ This is usually an oligoarthritis (Table 113-3),

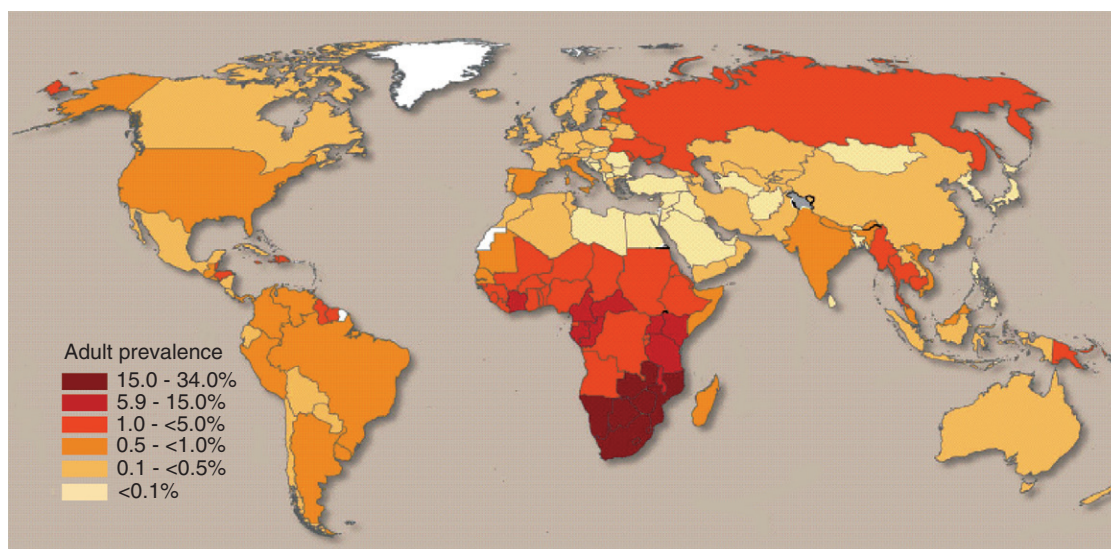

Figure 113-1 A global view of human immunodeficiency virus (HIV) infection—33 million living with HIV in 2007. (Extracted from 2008 Report on the Global AIDS Epidemic, UNAIDS, 2008.)

predominantly involving the lower extremities, and tends to be self-limited, lasting less than 6 weeks.^{2,4} Most commonly involved are the knees (84%), ankles (59%), and metatarsophalangeal joints (23%) in the lower limbs, and the wrists (41%), elbows (29%), and metacarpophalangeal and interphalangeal joints (25%) in the upper limbs, similar to other viral arthritides. Some patients have been reported as having a longer course, with joint destruction.^{5,6}

The origin is unclear; no association has been noted with HLA-B27 or any other known genetic factor. Synovial fluid cultures are typically sterile, although one report described the presence of tubuloreticular inclusions, suggesting a viral origin, possibly HIV itself.^{2,4} Radiographs of affected joints are usually normal, except in uncommon cases with prolonged symptoms, in which joint space narrowing and destruction can occur. Treatment includes nonsteroidal

anti-inflammatory drugs (NSAIDs) and, in more severe cases, low-dose glucocorticoids. Hydroxychloroquine and sulfasalazine also have been used.⁷

Reactive Arthritis Occurring in HIV Infection

Early reports in the United States suggested that reactive arthritis occurred more commonly in the setting of HIV infection; however, later studies showed that this may be reflective of the sexually active nature of the population at highest risk for HIV infection.⁸ This contention is not borne out in studies from sub-Saharan Africa, where HLA-B27 is rare, as were reports of spondyloarthritis before the HIV epidemic. With the arrival of AIDS, a dramatic upsurge in the prevalence of reactive arthritis and undifferentiated spondyloarthritis, and less often psoriatic arthritis,^{6,9} was seen, suggesting a pathogenic role of HIV infection.
